Agents' Strategic Behavior in Optimal Risk Sharing

Abstract. We consider the market of n financial agents who aim to increase their utilities by efficiently sharing their random endowments. Given the endogenously derived optimal sharing rules, we address the situation where agents do not reveal their true endowments, but instead they report as endowments the random quantities that maximize their utilities when the sharing rules are applied. Under mean-variance preferences, it is shown that each agent should share only a fraction of his true endowment and report that he is exposed to some endowment he does not possess. Furthermore, if all agents follow similar strategic behavior, the market equilibrates at a Nash-type equilibrium which benefits the speculators and results in risk sharing inefficiency. This agents' strategic behavior, when applied to oligopoly markets of exogenously given financial securities, changes the effective market portfolio and implies a price pressure on the traded securities in the CAPM.

Keywords: Optimal risk sharing, risk sharing games, Nash equilibrium in risk sharing, oligopoly financial markets, variations of CAPM.

1 Introduction

The concept of risk sharing is central in a large variety of financial fields ranging from structured finance to insurance and derivative trading. Its importance stems from the fact that investors, credit institutions and insurers find that sharing of investment random payoffs, defaultable incomes and insurance liabilities is often mutually beneficial in terms of reduction of risk exposures. The search for the best way to share risk is connected to financial innovation, in the sense that such sharing is fulfilled by designing and trading new financial securities.

The large majority of the growing body of research on complete and incomplete risk sharing markets assumes that agents act as *perfect competitors* and the induced equilibrium is of Pareto type. However, when trading of securities consists of few agents or when some of them have strong market power, the actions of each individual one clearly influence the outcome of the market. Market models that do not take into account this fact lead to equilibria that overestimate the efficiency of this market (and using the terminology of Hellwig (1980) and Kyle (1989), they require agents to behave "schizophrenically" by ignoring that their ability to affect the market). If we assume that agents do exploit their impact on the way the risk is shared, the equilibrium is different and the efficiency is reduced, since we go from Pareto to Nash-type equilibria. Although there is an extended literature studying a variety of different risk sharing markets, this important aspect has not been addressed. In this paper, we attempt to fill this gap by modelling the strategic behavior of agents when they share risk and analyzing the equilibria that occur as the outcome of these strategies.

We distinguish two settings under which participants share their risky endowments: the unconstrained and the constrained one. The former refers to the notion of *optimal risk sharing* in which agents complete the market by designing and trading financial securities that span the whole randomness of their endowments. Alternatively, a (partially optimal) risk sharing takes place when they trade at equilibrium a set of given securities whose payoffs are correlated to their endowments. Following the terminology of Magill and Quinzii (1996), we call this risk sharing transaction *constrained risk sharing* to emphasize that agents partially share their random incomes only by trading an exogenously given vector of financial securities and not the incomes themselves.

The optimal risk sharing problem is finding new financial assets which span the randomness of agents' endowments and whose allocation brings them to a Patero optimal condition (see the seminal works of Borch (1962, 1968), Wilson (1968), Demange and Laroque (1995) and the surveys of Allen and Gale (1994) and Duffie and Rahi (1995)). Motivated by the growing financial innovation and the ensuing increased establishment of new financial assets, many researchers have studied several theoretical aspects of risk sharing. For example Athanasoulis and Shiller (2000) point out the importance in terms of social welfare of sharing the whole aggregate endowment of an economy (even in a worldwide scale), Willen (2005) studies the changes of the prices of the existing assets when the risk sharing is facilitated by new financial assets and Acharya and Bisin (2005) focus on the effect of the restricted participation on the incomplete risk sharing market.[1]

---

[1] The challenging mathematical problem of the existence of the efficient allocations and the determination of the factors that characterize them have been recently studied by many authors under quite general preferences and market models (see among others Barrieu and El Karoui (2005), Jouini et al (2008), Dana (2011) and the references therein).

However, this literature has paid no attention to the realistic situations in which agents are able to affect the market equilibrium and, in order to exploit this ability, they act strategically. As mentioned above, this is a crucial part of modelling risk sharing transactions when the number of participating agents is relatively small and their market should be considered as *oligopoly*, rather than perfect competition. In the first part of this paper, we focus on an one-shot risk sharing market and model the agent's strategy by asking: *How much risk should an agent share?* In our line of arguments, it is supposed that agents agree on the sharing rules that optimally allocate the submitted endowments (that is the solution of the optimal risk sharing problem). We then take the position of an individual agent who has learned the endowments the other agents are going to share. Since his criterion is the maximization of his (individual) utility, it is reasonable to assume that he is *not* going to reveal and hence share his true endowment, but rather he is going to report as endowment the random payoff that maximizes his utility when the optimal rules are applied. Adapting the analogous game theory terminology, we call this reported random variable the agent's *best endowment response* (which in principle depends on the mechanism of the optimal sharing rules and the endowments of the rest of the participants in the market).[2]

Under mean-variance preferences, it is shown that it is almost never optimal for an agent to reveal his true risk exposure. Instead, his best endowment report is the sum of only a fraction of his true endowment and a proportion of the rest of the agents' aggregate endowment. In other words, according to this strategic behavior, an agent should report that he is exposed to risk he does not possess and only a part of the risk he does possess. Although the structure of the optimal contracts is unaffected, the associate cash transfers are influenced since the equilibrium prices depends the submitted risks. One of the interpretation of this strategy is that by submitting such exposures, he decreases the supply of the contracts he goes short and decreases the demand of those he goes long (a strategy that has direct desirable consequences on the equilibrium prices). The agent leaves more of his risk exposure unhedgeable but he gets in exchange better cash transfer. As expected, this behavior is more intense for agents with low risk aversion and furthermore the difference between the best response and the true endowment goes to zero as agent becomes more and more risk averse.

Reporting of the best endowment response however may be disadvantageous for reasons beyond the utility maximization criterion. For example, some of the other agents' endowment may be of a special type (investment payoff based on certain business, large short position on certain credit derivatives, incomes from defaultable bonds etc). If an agent reports that he is exposed to those risks, the conditions of the collaboration with the other agents may be deteriorated, in the sense that they will consider him more as a speculator than a hedger (and thus his participation decreases the efficiency of the sharing). In these situations, agent can alternatively restricts his choice to the percentage of his true endowment that he is going to submit for sharing. As before, the optimal percentage of his true endowment, which shall be called *best percentage response*, is the one that maximizes his utility after the transaction of the optimal financial assets. As proved in Section 3, this percentage is almost never equal to one and it can well be zero or even higher than one. The main factor that determines its value is the correlation between the true endowment and the other agents' aggregate endowment (higher correlation implies higher percentage). For example, an agent takes only speculator position (he doesn't submit any risk exposure) if this correlation is negative enough and other agents' endowments are very risky (when the risk is measured by variance). The underlying idea of this strategy is that the agent exploits the intense hedging demand of the other agents and gets better cash compensation. On the other hand, in the case of positive correlation, the agent may report overexposure to his endowment and sell short more than he owns in order to end up with a position of low variance.

---

[2] Recently, there is a number of papers studying the game theoretic structure of risk sharing and security markets. The majority of these papers focuses on the so-called *adverse selection problem* of the principle agent in risk sharing games (see for instance Page and Monteiro (2003, 2007) and Horst and Moreno-Bromberg (2008, 2012)).

The next question that one should ask is whether and how the market equilibrates when all agents follow the aforementioned types of strategies. Given the mechanism that share endowments, each agent reports the endowment that is willing to share (the one indicated by the best response). Since the reported endowment of each of them depends on the aggregate reported endowment of the others, agents will proceed to a sequel of negotiation about their "share-to-be" endowments, and the (Nash) equilibrium will be achieved at the point where this renegotiation reaches a fixed point. In situations where the number of agents is not sufficiently large to justify the setting of perfect competition, this market equilibrium is much more suitable. These markets should be considered as oligopolies and their equilibrium is the outcome of agents' reactions when each one acts according to his own optimization criterion. Although the *strategic market games* have captured a large research (see for instance Giraud (2003), Giraud and Weyers (2004) and the references therein), to the best of our knowledge, the rich literature in financial risk sharing has not modelled such situations.[3]

In Section 4, we define the *Nash risk sharing equilibrium* and provide its characterization under mean-variance preferences. The Nash equilibrium differs to the Pareto one in a number of aspects. First, the aggregate shared endowment (also called *effective*) is equal to the true aggregate endowment if and only if agents are homogeneous (all have the same risk aversion coefficient). Even in this case however, the risk allocation rules are different from the optimal ones in any non trivial cases. Although in Nash equilibrium the aggregate utility is reduced, for agents with sufficiently low risk aversion this transaction gives higher utility, when compared to the Pareto equilibrium transaction. In other words, this strategic game is more preferable for agents closer to risk neutrality and the speculators. Therefore, the utility loss of an agent that is caused by the Nash game is higher when he shares his risk with less averse agents.

On general, when an agent wants to share his risk exposure he should do so with agents with sufficiently different endowments and with high risk aversion levels (that is he should prefer hedgers than speculators). If the risky portfolios that are going to be shared are not very distinct (i.e., their correlations are positive), then the agents will prefer to trade with agents of at least the same risk aversion. Eventually, for transactions that involve transfer of low risk, agents tend to form subgroups of homogeneous only participants, where the utility loss is equally shared among them.

---

[3] In Rahi and Zigrand (2009) a security design game played among arbitrageurs is introduced and analyzed. The induced Nash equilibrium is optimal for the arbitrageurs regarding their profits from the mispricings across different market segments. Although the arbitrageurs' strategic behavior has some common features with the model presented here (e.g., it refers to maximization of quadratic utility functions), the game is played on different field (arbitrageurs imperfectly compete on the profits that come as a result of segmented markets and they do not share any risky exposure).

The fact that the aggregate utility is less than its maximum value means that the allocation of risk is inefficient. Following the related literature (see among others Acharya and Bisin (2005)), we define as *risk sharing inefficiency* the difference between the aggregate utility at the optimal risk sharing and the aggregate utility when the strategic game is played among agents. This inefficiency is strictly positive and approaches zero as the number of agents increases to infinity.

A similar Nash-type of equilibrium holds in the case where agents' best responses are the percentage of their true endowments. The only difference is that agents negotiate only the size of the endowment that are going to share and not its direction. As before, there are specific situations where agents prefer this renegotiation game (see for example Figures 3 and 4). In general though, the agents with low risk aversion gets higher utility and a similar interaction of the risk aversion coefficients holds and implies the eventual formation of sub-markets of homogeneous agents.

However, there are rare real-world situations where the transactions indicated by the optimal risk sharing rules are feasible. There is a number of exogenous reasons for this, such as the strict regulation in OTC markets (see for instance the related discussions in Awrey (2010), Duffie and Zhu (2011) and de Meijer and Wilson (2010)) and the important transaction costs (see among others Willen (2005) and Athanasoulis and Shiller (2000)). In these cases, agents can indirectly share their risks not by designing and pricing new (optimal) contracts, but instead by trading an exogenously given vector of standardized securities (such as derivatives, structured bonds, standard reinsurance contracts etc) and hence exploit in a way their correlation with their portfolios. Thus, the sharing market is *constrained* and its one-shot equilibrium trading refers to the prices and allocations of the securities that clear out the market. Under mean-variance preferences, this Pareto equilibrium coincides with the Capital Asset Pricing Model (hereafter CAPM) (see Magill and Quizii (1996) or Willen (1997) for an overview and Vanden (2004) for its extension under nonnegative wealth constraints and presence of options)[4]. An initial result about this equilibrium is that the utility of each agent after the optimal risk sharing transaction is always higher than the utility after the equilibrium transaction of a constrained market (for any given vector of securities that doesn't belong in the span of agents' endowments). In other words, *all agents suffer some utility loss when the risk sharing is constrained.*

When the agents take advantage of their ability to influence the prices, the demand schedule of each one may heavily affect the equilibrium price/allocation of the tradable assets which gives to the agents a strong motive to act strategically. We model the agents' strategic behavior in this setting by following similar arguments with the ones discussed above. More preciously, we consider an individual agent who learns the aggregate demand schedule of the rest of the agents[5] and we ask: *Which is his best equilibrium prices of the tradeable securities given the demand of the rest of the agents?* As before, the word "best" corresponds to the maximization of his quadratic utility. The agent then submits the specific demand function (called *best demand response*) that makes the market equilibrate at his preferable prices. The main idea of this market manipulation model is the one introduced in the seminal work of Kyle (1989). In this paper, Kyle distinguishes the agents to informed and uniformed speculators and examines how the market equilibrium is formed when they act after taking into account their impact on the prices. In his model, the reason that drives the agents to trade is the exploitation of the different information on a single tradeable asset. In the present paper however, it is the agents' different random endowments that make them proceed in transactions aiming to reduce their risk exposures. In Section 3, it is shown that this best response problem is closely related to the best endowment response one. In particular, the best response demand of an agent is the one that he would ask if his endowment were equal (up to constants) to his best endowment response (a fact that holds for any vector of tradeable assets).

---

[4] For the form of this equilibrium under general preferences, we refer the reader to Anthropelos and Žitković (2010), Horst et al (2010) and Cvitanic et al (2011).

[5] Under the mean-variance preferences, the demand schedules are linear and hence a demand function can be inferred by knowing only one value of it and the associated risk aversion level.

If all agents follow this strategy in order to drive the market prices, the induced equilibrium is of Nash type and has the same theoretical structure as the Nash endowment equilibrium. As in the setting of Kyle (1989), agents submit their demands for the tradable assets in a way that looks like a Walrasian auction. Each agent's reported demand makes the market equilibrate at his preferable prices given on the others' aggregate demand. Then another agent resubmits his demand based on the new aggregate demand and the auction ends when none of them has a motive to change the prices. Under mean-variance preferences, this Nash equilibrium can be considered as a *variation of the CAPM*, when the securities market is an oligopoly and each agent affects the price by renegotiating his demand function. There are many examples where this way of modelling security equilibrium prices is more suitable. In fact, every primary security trading, OTC derivative transaction involving agents with strong market power and negotiations of private placement investments should include a similar strategic behavior applied by the participants.

Since the best demand response of each agent is the one that corresponds to his best endowment response, it is reasonable to assume that the Nash equilibrium prices will be connected with the Nash risk sharing equilibrium. Indeed, the covariance part of the prices in CAPM is changed since the considered aggregate endowment (the so-called market portfolio) equals to the effective aggregate endowment in the Nash endowment game. This implies that *the Nash equilibrium price coincides with the Pareto equilibrium price if and only if agents are homogeneous*. Even in this case however, the Nash equilibrium allocation has less volume, a fact that decreases the aggregate utility. Furthermore, we are able to provide an exact measure of the *price pressure* that is caused as a result of the game played among agents. For example, an intense upward price pressure occurs when the agents with high hedging demand have also high risk aversion. Similarly to our previous Nash equilibria, speculators benefit from the Nash game (especially when the demand of hedgers is intense). These agents would prefer to trade these assets with agents with higher or at least equal risk aversion in order to improve their utility transaction outcomes. As argued above, if the volume of the transactions are small (something that stems from similar or low risk endowments) agents will tend to trade in separated sub-markets that consist only of homogeneous participants. Finally, as it is expected, the differences of Nash and Pareto equilibrium vanishes as the number of agents increases to infinity.

The paper proceeds as follows: Section 2 introduces the market model, the agents' decision criteria, the induced demand functions for any vector of securities and the Pareto equilibria in constrained and unconstrained risk sharing markets. Section 3 establishes the strategic behavior of each individual agent regarding the risk that he should share in three different market settings. The induced risk sharing equilibria when all agents follow similar strategies are defined and discussed in Section 4. We summarize the contributions of the paper in Section 5. For the reader's convenience, the proofs are omitted from the main body of the paper and given at the Appendix A.

2 Optimal Risk Sharing Equilibria

We consider a two-period market model of n financial agents aiming to reduce their risk exposures by executing a transaction. Throughout this manuscript it is assumed that there exists an exogenously priced numéraire in units of which all the mentioned financial quantities are denominated.

Each agent has already been exposed to a risk, which shall be called *random endowment* (also called *random income*, *labor income* or *business income*). This quantity incorporates the net discounted payoffs of all the unhedgeable financial positions that each agent has taken with maturity up to a given future time horizon T (their risk cannot be hedged out by trading in any market outside this setting). These endowments will be denoted through random variables $\mathcal{E}_i$, $i \in \{1, ..., n\}$ which are defined in a standard probability space $(\Omega, \mathcal{F}, \mathbb{P})$[6]. The sum of these random endowments is called the *aggregate endowment* and is denoted by $\mathcal{E} = \sum_{i=1}^{n} \mathcal{E}_i$. Below, $\mathcal{X}$ denotes the set of discounted payoffs of all *possible* financial positions and is assumed to be a linear subspace of $\mathbb{L}^2(\Omega, \mathcal{F}, \mathbb{P})$ (that is, the set all squared integrable random variables, hereafter denoted simply by $\mathbb{L}^2(\mathcal{F})$).

The preferences of agent i are given by *mean-variance utility* (hereafter M-V)

$$\mathbb{U}_i(X) = \mathbb{E}[X] - \gamma_i \, \mathbb{V}\mathrm{ar}[X] \tag{1}$$

where the constant $\gamma_i > 0$ is his *risk aversion coefficient* and $\mathbb{E}[\cdot]$ and $\mathbb{V}\mathrm{ar}[\cdot]$ are the expectation and variance maps under probability measure $\mathbb{P}$. Given his random endowment $\mathcal{E}_i$, agent i evaluates any financial position $X \in \mathcal{X}$ using his (adapted to endowment) utility

$$\mathcal{X} \ni X \mapsto \mathbb{U}_i(X + \mathcal{E}_i).$$

He is aiming to take short/long positions on securities with payoffs in $\mathcal{X}$ that maximizes his utility

$$\sup_{X \in \mathcal{X}} \mathbb{U}_i(X + \mathcal{E}_i) \tag{2}$$

A standard utility maximization well-studied example is when there exist k financial securities available for trading, $\mathbf{C} = (C_1, C_2, ..., C_k) \in (\mathbb{L}^2(\mathcal{F}))^k$, which prices are given by a vector $\mathbf{p} \in \mathbb{R}^k$, that is $\mathcal{X} = \{\mathbf{a} \cdot (\mathbf{C} - \mathbf{p}) : \mathbf{a} \in \mathbb{R}^k\}$. Then, problem (2) becomes

$$\sup_{\mathbf{a} \in \mathbb{R}^k} \{\mathbb{U}_i(\mathbf{a} \cdot \mathbf{C} - \mathbf{a} \cdot \mathbf{p} + \mathcal{E}_i)\} = \sup_{\mathbf{a} \in \mathbb{R}^k} \{\mathbb{U}_i(\mathbf{a} \cdot \mathbf{C} + \mathcal{E}_i) - \mathbf{a} \cdot \mathbf{p}\}. \tag{3}$$

---

[6] $\mathbb{P}$ is the so-called "*subjective*" probability measure, and is assumed to be common for each agent. Removal of this homogeneous beliefs assumption doesn't change the general concept of this paper, although it adds a great deal of complexity in calculations. For a study on the effect of ambiguity in risk sharing, we refer the reader to Strzalecki and Werner (2011).

The set of vectors $\mathbf{a} \in \mathbb{R}^k$ that maximize (3) for a given price vector $\mathbf{p}$ is the *demand* of agent i on $\mathbf{C}$ at price $\mathbf{p}$ (hereafter denoted by $Z_i(\mathbf{p})$), i.e.

$$Z_i(\mathbf{p}) = \underset{\mathbf{a}\in\mathbb{R}^k}{\operatorname{argmax}} \{\mathbb{U}_i(\mathbf{a}\cdot\mathbf{C} + \mathcal{E}_i) - \mathbf{a}\cdot\mathbf{p}\} \tag{4}$$

The decision criterion (4) implies a number of assumptions, namely: (i) there is no budget constraints, i.e., agents are able to borrow units of numéraire without changing their utility status, (ii) there is no short selling constraints on securities in $\mathbf{C}$, and (iii) there are no further transaction costs. Although the last assumption is standard in the literature, the first two required some justification. It should be mentioned that these assumptions are taken in the view of risk sharing arguments, which means that any transfer of cash is summed up to zero. Furthermore, one may think that the absence of short selling constrains implies the possibility of unbounded supply; however, this can well be avoided by imposing regularity constraints on the set of admissible positions $\mathcal{X}$. Unbounded supply is indeed the case if the price is extremely high (or low), however the equilibrium arguments that follow will endogenously exclude this situation.

Optimization problem (4) is a fundamental portfolio choice problem that has been analyzed by a number of authors (see among others Cochrane (2005) for an overview in the case of quadratic utility and budget constraints and Gârleanu et al (2009), Acharya et al (2012) and Anthropelos and Žitković (2010) for applications of this problem to pricing financial securities).

For the set $Z_i(\mathbf{p})$ to be a singleton for any price vector $\mathbf{p}$ it is sufficient to impose the following standing assumption.

Standing Assumption 1. *For every mentioned vector of securities* $\mathbf{C}$, *the matrix* $\mathbb{V}\mathrm{ar}[\mathbf{C}]$ *is non-singular.*

Under this assumption, $Z_i(\mathbf{p})$ is a function from $\mathbb{R}^k$ to $\mathbb{R}^k$ which shall be called the *demand function* (of demand schedule) of agent i of securities $\mathbf{C}$ and is given by

$$Z_i(\mathbf{p}) = \left(\frac{\mathbb{E}[\mathbf{C}] - \mathbf{p}}{2\gamma_i} - \mathbb{C}\mathrm{ov}(\mathbf{C}, \mathcal{E}_i)\right) \cdot \mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}] \tag{5}$$

where $\mathbb{E}[\mathbf{C}]$ stands for the vector $(\mathbb{E}[C_1], ..., \mathbb{E}[C_k])$ and for any payoff $X \in \mathbb{L}^2(\mathcal{F})$, $\mathbb{C}\mathrm{ov}(\mathbf{C}, X)$ denotes the vector $(\mathbb{C}\mathrm{ov}(C_1, X), ..., \mathbb{C}\mathrm{ov}(C_k, X))$. Note that the demand has two distinguished sources, namely the risk premium scaled by agent's risk aversion, $\frac{\mathbb{E}[\mathbf{C}]-\mathbf{p}}{2\gamma_i} \cdot \mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}]$, and the correlation between the tradeable securities and the agent's endowment, $\mathbb{C}\mathrm{ov}(\mathbf{C}, \mathcal{E}_i) \cdot \mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}]$ (see also Demange and Laroque (1995) and Willen (2005) for analogous and more detailed discussion). It is clear that absolute size of the demand function is a decreasing function of the risk aversion coefficient, γ_i. This means that the more risk averse the agent becomes the less willing she is to participate in a transaction on $\mathbf{C}$. Also, the demand for a particular security C_j (for $j \in \{1, ..., k\}$), is a decreasing function of the covariance of C_j with agent's endowment. This supports the use of the M-V evaluation for risk management purposes. Indeed, we expect that when the covariance of particular security is a large negative number, the agent would be willing to take long position on this security, since this would decrease the risk exposure created by the random endowment. Finally, an observation of the same nature is that $|Z_{i,j}(\mathbf{p})|$ is decreasing with respect to $\mathbb{V}\mathrm{ar}[C_j]$, i.e., the riskier the security becomes, the smaller the desired position on it is.

2.1 Optimal risk sharing

We now address the main subject of this manuscript, namely how agents can mutually reduce their risk exposures by proceeding to certain types of transactions. In our over-the-counter transaction setting, we assume that each agent shares his random endowment with the other agents aiming to reduce his risk or equivalently increase his expected utility. This is a general picture of the risk sharing problem and in the case where there is no exogenous constrain or additional transaction costs, agents freely negotiate the design of contracts that "*optimally*" share their risk exposures. The word optimally refers to a Pareto-type of transaction. More precisely, we define the set $\mathcal{A} = \{\mathbf{C} \in (\mathbb{L}^2(\mathcal{F}))^n : \sum_{i=1}^n C_i = 0\}$ which contains all the possible sharing rules of agents' endowments, where C_i^* is the payoff of the contract that agent i is going to receive at the terminal time. The formal definition of the optimal risk sharing is the following.

Definition 1. *The vector of securities* $\mathbf{C}^* \in \mathcal{A}$ *is a Pareto optimal risk sharing if for all* $\mathbf{C} \in \mathcal{A}$ *the following implication holds true*

If for some $i \in \{1, ..., n\},\ \mathbb{U}_i(\mathcal{E}_i + C_i) > \mathbb{U}_i(\mathcal{E}_i + C_i^*) \Rightarrow \exists j \in \{1, ..., n\}, j \neq i$ *s.t.* $\mathbb{U}_j(\mathcal{E}_j + C_j) < \mathbb{U}_j(\mathcal{E}_j + C_j^*)$

The requirement that the sum of these contracts is zero implies that risk sharing does not add further risk in the market (the net supply is zero). As it implied by the results in Demange and Laroque (1995) (see also Jouini et al (2008) for a similar result under more general risk preferences), a useful characterization of the optimal risk sharing rules is that $\mathbf{C}^* \in \mathcal{A}$ solves the following maximization problem[7]

$$\max_{\mathbf{C} \in \mathcal{A}} \sum_{i=1}^{n} \mathbb{U}_i(\mathcal{E}_i + C_i) \tag{6}$$

The problem of optimal risk sharing has captured a large amount of literature in finance and economics. It can be considered as a structured financial problem in the sense that the optimal sharing rules are financial securities that are structured to satisfy certain hedging needs. For a circumstantial discussion on the theoretical approach on this issue and its connection to financial innovation, we refer the reader to Allen and Gale (1994) and Duffie and Rahi (1995).

In every practical situation however, the optimal contracts do not take complex forms, that is the solution $\mathbf{C}^*$ of (6) is not a complicated function of $\mathcal{E}_i$'s. In fact, for practical purposes, we may restrict to linear sharing rules, i.e., instead of looking at problem (6), a more practical perspective suggests the following one

$$\max_{A \in \mathbb{A}_n} \sum_{i=1}^{n} \mathbb{U}_i(\mathcal{E}_i + \mathbf{a}_i \cdot \mathbf{E}) \tag{7}$$

where $\mathbf{E} = (\mathcal{E}_1, \mathcal{E}_2, ..., \mathcal{E}_n)$, $\mathbb{A}_n$ is the set of square matrices of dimension n that represent the allocations of securities in $\mathcal{X}^n$ and $\mathbf{a}_i \in \mathbb{R}^n$ are their rows. In other words, for each allocation $A \in \mathbb{A}_n$, the element a_{ij} denotes the units of security $\mathcal{E}_j$ that agent i holds (negative a_{ij} means short position). Hence, vector $\mathbf{a}_i \in \mathbb{R}^n$ stands for vector $(a_{i1}, ..., a_{in})$ and indicates the units of each security in $\mathbf{E}$ agent i holds (and hence $\sum_{i=1}^n \mathbf{a}_i = \mathbf{0}$).

---

[7] These optimal sharing rules are consistent with the social welfare optimization (see among others Acharya and Bisin (2005) for related discussion).

For general utilities problems (6) and (7) are not necessarily equivalent and the existence of a solution of one does not imply the solution of the other[8]. However, in the case of M-V preferences both have a common solution (see also Demange and Laroque (1995), Athanasoulis and Shiller (2000) and Barrieu and El Karoui (2005)).

Proposition 1. *The unique (up to constants) optimal risk sharing rule is given by the vector of securities* $\mathbf{C}^* = (C_1^*, ..., C_n^*)$ *with*

$$C_i^* = \mathbf{a}_i^* \cdot \mathcal{E} \tag{8}$$

where elements of vector $\mathbf{a}_i^* = (a_{i1}^*, a_{i2}^*, ..., a_{in}^*)$ *are given by*

$$a_{ii}^* = \frac{\gamma - \gamma_i}{\gamma_i} \qquad \text{and} \qquad a_{i\zeta}^* = \frac{\gamma}{\gamma_i}, \;\; \text{for } \zeta \neq i, \tag{9}$$

where, γ *is the aggregate risk aversion coefficient, i.e.* $\gamma = \left(\sum_{i=1}^{n} \frac{1}{\gamma_i}\right)^{-1}$. *Furthermore, the allocation* $A^* = (a_{ij}^*) \in \mathbb{A}_n$ *is the optimal allocation for vector* $\mathbf{E}$*, i.e.* A^* *solves problem* (7).

Note that this optimal sharing rule is independent on the distribution of the endowments which simply reflects the fact that agents have the same beliefs (common probability measure) and evaluate payoffs following similar lines (common type of utility). The interpretation of sharing rule (8) and (9) is clear. Agent i is going to short a part of his endowment and long equal part of the other agents' random endowments. The prices of these transactions however can not be induced by the problem (6) (or problem (7))

The aggregate maximized utility of the optimal risk transaction is given by

$$\sum_{i=1}^{n} \mathbb{U}_i(\mathcal{E}_i + C_i^*) = \mathbb{E}[\mathcal{E}] - \gamma \, \mathbb{V}\mathrm{ar}[\mathcal{E}]$$

which is sometimes called the utility of the *representative agent*, which also has M-V preferences and his endowment and risk aversion coefficient are the aggregate ones. Furthermore, the difference

$$\sum_{i=1}^{n} \mathbb{U}_i(\mathcal{E}_i + C_i^*) - \sum_{i=1}^{n} \mathbb{U}_i(\mathcal{E}_i) = \sum_{i=1}^{n} \gamma_i \, \mathbb{V}\mathrm{ar}[\mathcal{E}_i] - \gamma \, \mathbb{V}\mathrm{ar}[\mathcal{E}] \tag{10}$$

is the *maximized aggregate gain* of utility that the market (or the representative agent) enjoys by the optimal risk sharing transaction.

2.2 Constrained risk sharing and equilibrium pricing

As discussed in the introductory section, the construction of contracts that optimally share the risky endowments among the agents is not always possible. Examples of the exogenous reasons that restrict agents from the transaction of the optimal risk sharing contracts are: (i) Stricter regulation, regarding OTC transactions, states new restrictions on credit levels, which cannot be met after the optimal risk sharing transaction. The reason for this is that risk measurement that is used by agents and investors is usually different than those used by the regulators (for instance, problems (6) and (7) do not include credit constrains or margin account requirements). This makes the optimal risk sharing very expensive in the sense that the agents should commit part of their capital as additional margin accounts. (ii) Some types of random incomes are indivisible due to their nature and the difficulties in their modelling as random variables, e.g. real estate investments, revenues of a running business, dividends from illiquid shares etc. (iii) In some cases, sharing of endowment is against the general policy of an agent, for example selling part of his endowment may imply a message of lack of trust to his clients on which the endowment payoffs are based. (iv) Further liquidity concerns and transaction costs may make the optimal risk sharing trading disadvantageous.

---

[8] For Von-Neumann-Morgenstern utility functions the equivalence of problems (6) and (7) holds if and only if the risk tolerances of all agents are linear and have the same marginal risk tolerance coefficient (see Chapter 3 of Magill and Quinzii (1996) for the proof).

Under these realistic conditions, agents can reduce their unhedgeable risk exposures by writing standardized contracts whose payoffs are somehow correlated to their endowments and let them be traded among other agents. These securities could be any structured financial derivative products, such as credit derivatives, asset backed securities, reinsurance contracts etc. Note that issuing of securities is not Pareto-optimal (agents do not collaborate in the designing as in problems (6) and (7)). However, agents allocate and price these securities and hence exploit the payoff correlation with their endowments for risk management purposes.

We assume that there is a finite number of these securities and their payoffs belong to the set of possible financial positions $\mathcal{X}$. Their payoffs shall be denoted by the random vector $\mathbf{C} = (C_1, ..., C_k) \in \mathcal{X}^k$. Given these payoffs, agents negotiate the prices and the quantities of the given securities in $\mathbf{C}$ they will trade. We in fact follow the lines of problem (7) where instead of $\mathbf{E}$, agents maximize the sum of their utilities by trading vector $\mathbf{C}$. The set of allocations of $\mathbf{C}$ among agents will be denoted by $\mathbb{A}_{n\times k}$, that is $A \in \mathbb{A}_{n\times k}$ is a matrix in $\mathbb{R}^{n\times k}$, where its element a_{ij} denotes the number of security C_j that agent i holds ($i \in \{1, ..., n\}$ and $j \in \{1, ..., k\}$) and $\sum_{i=1}^{n} \mathbf{a}_i = \mathbf{0}$, where $\mathbf{a}_i$ is the i-th row of A.

The problem of risk sharing through vector of securities $\mathbf{C}$ is

$$(11) \qquad \sup_{A\in\mathbb{A}_{n\times k}, \mathbf{p}\in\mathbb{R}^k} \left\{ \sum_{i=1}^{n} \mathbb{U}_i(\mathbf{a}_i \cdot \mathbf{C} + \mathcal{E}_i) - \sum_{i=1}^{n} \mathbf{a}_i \cdot \mathbf{p} \right\} = \sup_{A\in\mathbb{A}_{n\times k}} \left\{ \sum_{i=1}^{n} \mathbb{U}_i(\mathbf{a}_i \cdot \mathbf{C} + \mathcal{E}_i) \right\}$$

It is clear that the above argument of optimal sharing provides only the allocation of $\mathbf{C}$ that maximizes the sum of agents utilities. In other words, due to the cash invariance property, maximization of sum of utilities does not provide the prices at which the optimal transaction on $\mathbf{C}$ will take place. Getting the consistent price vector for $\mathbf{C}$ (which is a crucial part of transaction) needs another argument. This can be based on the demand function for each of the agents. More precisely, we suppose that the transaction prices of elements of $\mathbf{C}$ will be those that make the sum of agents' demand functions equal to zero, or in other words the price that makes the risk sharing consistent are the ones that makes supply of $\mathbf{C}$ equal to its demand. More formally, we have the following definition of price-allocation equilibrium[9].

---

[9] This equilibrium setting for risk sharing has been applied in Anthropelos and Žitković (2010a) under the presence of an exogenously priced financial market (see also Anthropelos and Žitković (2010b) for the special case of exponential utility

Definition 2. *For a given vector of securities* $\mathbf{C} \in \mathcal{X}^k$*, the pair* $(\mathbf{p}^*, A^*) \in \mathbb{R}^k \times \mathbb{A}_{n\times k}$ *is called a price-allocation equilibrium if* $Z_i(\mathbf{p}^*) = \mathbf{a}_i^*$ *for each* $i \in \{1, ..., n\}$*.*

This equilibrium coincides with a Pareto-optimal pricing and allocation of $\mathbf{C}$ and is called *Pareto equilibrium price* of $\mathbf{C}$ (or *socially optimal equilibrium* of securities $\mathbf{C}$). It is easily checked that equilibrium allocation A^* (if exists) solves (11).

At equilibrium, each agent enjoys a level of utility that is higher or at least equal to his initial utility, that is $v_i(\mathbf{p}^*) \geq \mathbb{U}_i(\mathcal{E}_i)$ where the equality holds if and only if the equilibrium price vector coincides with agent's reservation price vector, $\mathbf{p}_i^0$. Given the vector of securities $\mathbf{C}$, we call the quantity $v_i(\mathbf{p}^*)$ the *utility level* at equilibrium of agent i. Note that the difference $v_i(\mathbf{p}^*) - \mathbb{U}_i(\mathcal{E}_i)$ measures the gain (in terms of utility) that agent i enjoys by entering into the equilibrium transaction of $\mathbf{C}$. The advantage of using $v_i(\mathbf{p}^*)$ is that it is measured in numéraire units and hence can be used for the comparison among different equilibria and agents.

Taking into account equation (5) we get the following representation of the CAPM (see also Willen (1997) and Athanasoulis and Shiller (2000)).

Proposition 2 (CAPM)**.** *The equilibrium price of a vector of securities* $\mathbf{C}$ *is given by*

$$\mathbf{p}^* = \mathbb{E}[\mathbf{C}] - 2\gamma\,\mathbb{C}\text{ov}(\mathbf{C}, \mathcal{E}) \tag{12}$$

and the equilibrium allocation A^* *is the matrix whose rows* $\mathbf{a}_i^*$ *are given by*

$$\mathbf{a}_i^* = \mathbb{C}\text{ov}\left(\mathbf{C}, C_i^*\right) \cdot \mathbb{V}\text{ar}^{-1}[\mathbf{C}] \tag{13}$$

for each $i \in \{1, ..., n\}$*, where* C_i^* *is given by* (8) *and* (9)*.*

Proposition 2 states that the equilibrium prices do not depend on the covariance matrix of securities, but only on their expectations and their covariances with the aggregate endowment (this covariance is usually called the *covariance value* of the securities). The equilibrium price of a security C_j increases as its covariance with the aggregate endowment decreases, something that reflects the higher demand of this particular security. Also, the vector of quantities that agent i is going to short/long at equilibrium has a clear link with the covariances of the traded securities and the contract that she would get if the optimal risk sharing were possible. The higher (in absolute terms) the covariance of the tradable security $\mathbf{C}$ and his optimal contract are, the higher is his demand (i.e., his participation in the market).

Our goal is to see how this equilibrium price-allocation influences individual agents' utility and how much of it he gains by participating in this transaction. The following proposition can be proved by simple calculations.

Proposition 3. *The utility level at equilibrium of agent* i *is given by*

$$v_i(\mathbf{p}^*) = \gamma_i\,\mathbb{C}\text{ov}(\mathbf{C}, C_i^*) \cdot \mathbb{V}\text{ar}^{-1}[\mathbf{C}] \cdot \mathbb{C}\text{ov}(\mathbf{C}, C_i^*) + \mathbb{U}_i(\mathcal{E}_i). \tag{14}$$

---

and $n = 2$). Similar equilibrium arguments has recently been supported by a number of papers in option and future markets (Acharya et at. (2012), Cvitanic et al (2011), Gârleanu et al (2009) and Horst et al (2010)).

It is implied that the gain of equilibrium transaction of agent i, that is the difference $v_i(\mathbf{p}^*) - \mathbb{U}_i(\mathcal{E}_i)$, is increasing with respect to the absolute size of his positions on $\mathbf{C}$.

Remark 1. *The term $\mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*) \cdot \mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}] \cdot \mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*)$ has a nice interpretation in the case where both $\mathbf{C}$ and $\mathbf{E}$ follow multivariate normal distribution. Under this assumption, it follows (see e.g. Chapter 3 of Muirhead (1982)) that*

$$\mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*) \cdot \mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}] \cdot \mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*) = \mathbb{V}\mathrm{ar}[C_i^*] - \mathbb{V}\mathrm{ar}[C_i^* | \mathbf{C} = c], \quad \textit{for every vector } c \in \mathbb{R}^k.$$

This implies that

$$v_i(\mathbf{p}^*) = \gamma_i \, \mathbb{V}\mathrm{ar}[\mathbb{E}[C_i^* | \mathbf{C}]] + \mathbb{U}_i(\mathbb{E}_i). \tag{15}$$

The representation (15) *is a way to see how agent i benefits from trading $\mathbf{C}$, given the endowments and the risk aversion level of the rest of the agents. Namely, the more uncertainty of C_i^* is revealed by $\mathbf{C}$, the higher the gain of utility of agent i from trading $\mathbf{C}$ is. Note that when C_i^* is measurable with respect to the information generated by $\mathbf{C}$, $v_i(\mathbf{p}^*)$ gets its maximum value, and when C_i^* is independent with $\mathbf{C}$, agents is indifferent between trading and not trading $\mathbf{C}$.*

Regarding the aggregate utility, the fact that the tradeable assets are not the agents endowments means that any other sharing transaction has less efficiency. The difference between the aggregate utility of the optimal risk sharing and the aggregate utility after the equilibrium sharing of $\mathbf{C}$ can be considered as a measure of the *risk sharing inefficiency.*

$$\text{Risk Sharing Inefficiency } = \sup_{\mathbf{X} \in \mathcal{A}} \left\{ \sum_{i=1}^{n} \mathbb{U}_i(\mathcal{E}_i + X_i) \right\} - \sup_{A \in \mathbb{A}_{n \times k}} \left\{ \sum_{i=1}^{n} \mathbb{U}_i(\mathbf{a}_i \cdot \mathbf{C} + \mathcal{E}_i) \right\} \tag{16}$$

More generally,

$$\text{Risk Sharing Inefficiency} = \text{Optimal Aggregate Utility } - \text{ Realized Aggregate Utility} \tag{17}$$

2.3 Equilibrium prices of endowments

A special case of problem (11) is when the securities available for trading are the agents' endowments ($\mathbf{C} = \mathbf{E}$). As shown in Proposition 2, when utilities are quadratic, this problem is equivalent to the optimal risk sharing problem (6), that is the market becomes *complete.* Hence, solution of (11) provides not only the optimal sharing contracts but also the equilibrium prices of the agents' endowments. By applying Proposition 2 for the vector of endowments $\mathbf{E}$, we get that

$$\mathbf{p}_{\mathcal{E}}^* = \mathbb{E}[\mathbf{E}] - 2\gamma \mathbf{1}_n \cdot \mathbb{V}\mathrm{ar}[\mathbf{E}] \tag{18}$$

where $\mathbf{1}_n$ is the vector of dimension n with all elements equal to 1. Straightforward calculations also give that the utility level of agent i after the optimal risk sharing is given by

$$v_i^o(\mathbf{p}_{\mathcal{E}}^*) = \gamma_i \, \mathbb{V}\mathrm{ar}[C_i^*] + \mathbb{U}_i(\mathcal{E}_i) \tag{19}$$

where, $v_i^o(\cdot)$ denotes the utility level of agent i when the tradable security vector is $\mathbf{E}$. The term $\gamma_i \, \mathbb{V}\mathrm{ar}(C_i^*)$ is the highest possible utility gain of agent i that he could get by trading in a Pareto-optimal way with the rest $n-1$ agents. Hence, the risk sharing inefficiency caused by equilibrium trading of vector of securities $\mathbf{C}$ is equal to

$$\sum_{i=1}^{n} \left(v_i^o(\mathbf{p}_{\mathcal{E}}^*) - v_i(\mathbf{p}^*)\right) = \sum_{i=1}^{n} \gamma_i \, \mathbb{V}\mathrm{ar}[C_i^*] - \sum_{i=1}^{n} \gamma_i \, \mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*) \cdot \mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}] \cdot \mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*) \tag{20}$$

It follows from (14) and (19) that the utility *"loss"* of each agent when the risk sharing is constrained, namely the difference

$$v_i^o(\mathbf{p}_{\mathcal{E}}^*) - v_i(\mathbf{p}^*) = \gamma_i \left(\mathbb{V}\mathrm{ar}[C_i^*] - \mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*) \cdot \mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}] \cdot \mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*) \right), \tag{21}$$

is always non-negative and equal to zero if and only if the optimal contract of agent i can be written as a linear combination of elements of $\mathbf{C}$. We state this fact in the following proposition the proof of which follows from standard arguments.

Proposition 4. *When the risk sharing is done through trading a vector of securities* $\mathbf{C} \neq \mathbf{E}$, *each agent suffers a loss of utility. This loss is zero for agent* i *if and only if there exist* $b \in \mathbb{R}$ *and* $\mathbf{a} \in \mathbb{R}^k$ *such that* $C_i^* = b + \mathbf{a} \cdot \mathbf{C}$, *where* C_i^* *is given by* (8) *and* (9).

Note that equation (21) states that agents with high risk aversion suffer more loss of utility because of constrains. In particular, when $n = 2$, agents' losses are proportional to each other, i.e.

$$\text{Loss of agent } 1 = \tfrac{\gamma_1}{\gamma_2} \text{ Loss of agent } 2.$$

3 The Risk that an Agent should Share

In this section, we argue that inefficiency of risk sharing markets is caused due to the strategic behaviors that agents may follow when negotiating the transaction of their endowments. In such situations, the equilibrium (if exists) is a Nash-type equilibrium, not a Pareto one, something that in principle implies a decrease in the aggregate utility (or equivalently inefficient risk sharing).

In the primary structured financial markets the participation of the agents is limited to a specific number of agents. Hence, the participation and the actions of each individual one definitely affects the point at which the market equilibrates. In a sense, these markets function at the primary phase as *oligopolies*. Therefore, when modelling such markets' equilibrium, one should involve not only the mechanism that leads to equilibrium, but also the participants' strategy that incorporates each agent's response to other agents' decisions. In what follows, we introduce a model of an individual agent's strategic behavior which is based on the equilibrium arguments of the previous discussion and we discuss their optimal reactions.

We assume that the n agents form a market in which they report their endowments and then (according to the induced sharing rules, described in (6)) the optimal-sharing contracts are designed, priced and traded among them. However, an agent may not report his true endowment but rather choose to report as his "shared-to-be" endowment a random variable that, when involved in the optimal trading procedure, would result in higher expected utility. The formulation of this problem is established into three market settings: (i) when agents negotiate the whole randomness of the endowments that are going to share, (ii) when they negotiate only a percentage of their true endowments and (iii) when they negotiate the price of a given vector of traded securities $\mathbf{C}$.

3.1 How much risk should an agent share?

We return to the Pareto optimal risk sharing setting, where agents design and price the contracts that are going to trade. The sharing mechanism that produces the optimal contracts and their prices are given by the solutions of problem (6) or problem (7) and are functions of agents' endowments. Given this transaction set up, we are asking whether it is preferable for an individual agent to report (and hence share) his true risk exposure or it is "*better*" to report as his endowment a different random variable. The word *better* refers to the level of the utility at equilibrium, i.e., quantity $v_i^o(\mathbf{p}^*)$. Let's take the position of agent 1, which enters the risk sharing market, where the way agents share their endowments is given by Proposition 1 and equations (9) and (18). Given that the rest of agents have reported endowments $\mathcal{E}_2, \mathcal{E}_3, ..., \mathcal{E}_n$, it is reasonable to assume that agent 1 may not report as his endowment $\mathcal{E}_1$, but another random variable $B \in \mathbb{L}^2(\mathcal{F})$. Since his decision criterion is the maximization of his expected utility, we argue that he is going to report as endowment the random variable that maximizes his level of utility when the transaction is proceeded. Following the game theory terminology, we shall call the optimal choice for reported endowment *best endowment response* of agent 1.

Below, we introduce and solve this problem by providing explicit and well-interpreted solutions. We adapt the risk sharing setting of problem (6) (or the equivalent problem (7)). If the reported endowments are $\mathcal{E}_1, ..., \mathcal{E}_n$, the optimal sharing rule states that agent 1 gets the payoff $C_1^* = \frac{\gamma}{\gamma_1}\mathcal{E}_{-1} - \frac{\gamma_1 - \gamma}{\gamma_1}\mathcal{E}_1$ and pays $\mathbf{a}_1^* \cdot \mathbf{p}_{\mathcal{E}}^*$, where $\mathbf{a}_1^*$ is given in (9) and $\mathbf{p}_{\mathcal{E}}^*$ in (18) (in what follows $\mathcal{E}_{-i}$ stands for $\sum_{j \neq i} \mathcal{E}_j$, for $i \in \{1, ..., n\}$). Therefore, given that the rest agents have reported endowments $\mathcal{E}_2, \mathcal{E}_3, ..., \mathcal{E}_n$, if agent 1 reports as his random endowment some random variable $B \in \mathbb{L}^2(\mathcal{F})$, then according to optimal sharing rule he would get contract with payoff

$$C_1^*(B) = \frac{\gamma}{\gamma_1}\mathcal{E}_{-1} - \frac{\gamma_1 - \gamma}{\gamma_1}B, \tag{22}$$

the accumulate cash transaction is

$$\mathbf{p}_1^*(B) = \left(-\frac{\gamma_1 - \gamma}{\gamma_1}, \frac{\gamma}{\gamma_1}, ..., \frac{\gamma}{\gamma_1}\right) \cdot \begin{pmatrix} \mathbb{E}[B] - 2\gamma\,\mathbb{C}\mathrm{ov}\,(B + \mathcal{E}_{-1}, B) \\ \mathbb{E}[\mathcal{E}_2] - 2\gamma\,\mathbb{C}\mathrm{ov}\,(B + \mathcal{E}_{-1}, \mathcal{E}_2) \\ \vdots \\ \mathbb{E}[\mathcal{E}_n] - 2\gamma\,\mathbb{C}\mathrm{ov}\,(B + \mathcal{E}_{-1}, \mathcal{E}_n) \end{pmatrix} \tag{23}$$

and his utility after the transaction would be

$$G_1(B; \mathcal{E}_{-1}) = \mathbb{U}_1(\mathcal{E}_1 + C_1^*(B) - \mathbf{p}_1^*(B)) = \mathbb{E}[\mathcal{E}_1 + C_1^*(B)] - \gamma_1\,\mathbb{V}\mathrm{ar}[\mathcal{E}_1 + C_1^*(B)] - \mathbf{p}_1^*(B). \tag{24}$$

Similarly, we define the utility level of agent i when he reports B and the rest of the agents have reported $\mathcal{E}_1, ..., \mathcal{E}_{i-1}, \mathcal{E}_{i+1} ..., \mathcal{E}_n$ and denote it by $G_i(B; \mathcal{E}_{-i})$ (the fact that the dependence is restricted to the aggregate endowment of the other agents is proved below).

Therefore, the best endowment response of agent i is the solution of the following maximization problem

$$\max_{B \in \mathbb{L}^2(\mathcal{F})} \{G_i(B; \mathcal{E}_{-i})\} \tag{25}$$

Note that best response should be a random variable in $\mathbb{L}^2(\mathcal{F})$, which implies that agent's reported endowment is measurable with respect to the information that is generated by the true endowments (there is no other security in the optimal risk sharing environment, see also the related discussion in the introductory section and Section 2). The solution of problem (25) is given in the following proposition.

Proposition 5. *The unique (up to constants) best endowment response of agent i when the rest of the agents have reported endowments* $\mathcal{E}_1, ..., \mathcal{E}_{i-1}, \mathcal{E}_{i+1}, ..., \mathcal{E}_n$ *is given by*

$$B_i^* = \frac{\gamma_i}{\gamma_i + \gamma} \mathcal{E}_i + \frac{\gamma^2}{\gamma_i^2 - \gamma^2} \mathcal{E}_{-i} \tag{26}$$

for each $i \in \{1, ..., n\}$.

If agent i chooses to share his best endowment response, the optimal risk sharing rule implies that he is going to get the contract with payoff

$$C_i^*(B_i^*) = \frac{\gamma}{\gamma_i + \gamma} \mathcal{E}_{-i} - \frac{\gamma_i - \gamma}{\gamma_i + \gamma} \mathcal{E}_i,$$

instead of

$$C_i^* = \frac{\gamma}{\gamma_i} \mathcal{E}_{-i} - \frac{\gamma_i - \gamma}{\gamma_i} \mathcal{E}_i.$$

This gives that

$$C_i^*(B_i^*) = \frac{\gamma_i}{\gamma_i + \gamma} C_i^*.$$

Hence, the best optimal contract of agent i is in fact a percentage of the contract that the optimal risk sharing procedure induces. The factor $\frac{\gamma_i}{\gamma_i + \gamma}$ is increasing in γ_i meaning that the less the risk aversion, the less percentage of the optimal contract the agent gets (clearly, this percentage increases as the number of agents increases).

At this point, a number of observations worth some attention. First, the best response B_i^* does not depend on any of the moments of the endowments and hence it is model free in the sense of probability distribution of the random endowments. Given that agent i knows the endowments of the rest of the agents, he should report as his endowment a certain percentage of his true endowment and a factor of the other agents' aggregate endowment (a risk that he doesn't possess). Note that the factor $\frac{\gamma^2}{\gamma_i^2 - \gamma^2}$ in front of the aggregate endowment of the rest of the agents is a decreasing function of the risk aversion coefficient γ_i. In fact, it is straightforward to check that the limit of B_i^* is equal to $\mathcal{E}_i$ as γ_i goes to infinity and becomes unbounded as γ_i goes to zero. We may conclude then that problem (25) is more intense for low risk averse agents and in a sense it reflects a *speculating attitude* in their strategic behavior. As expected, the difference between B_i^* and $\mathcal{E}_i$ reduces as the number of participating agents increases.

Interpreting this strategic behavior, one can argue that agent i leaves some of his risk exposure unhedgeable in order to get higher cash transfer (better endowment prices) given the hedging demand of the rest of the agents. We calculate that his utility level after reporting the best endowment response is

$$G_i(B_i^*; \mathcal{E}_{-i}) = \frac{\gamma_i^3}{\gamma_i^2 - \gamma^2} \, \mathbb{V}\mathrm{ar}\left[C_i^*\right] + \mathbb{U}_i(\mathcal{E}_i)$$

which means that the increase of agent i utility from following this strategic behavior is equal to $\gamma_i \, \mathbb{V}\mathrm{ar}[C_i^*]\frac{\gamma^2}{\gamma_i^2-\gamma^2}$ or in other words, compared to (19), the percentage increase of utility after following strategy of problem (25) is $\frac{\gamma^2}{\gamma_i^2-\gamma^2}$. This equals to $\frac{1}{n^2-1}$ for homogenous agents (33% for $n = 2$, 12.5% for $n = 3$ etc).

3.2 Which percentage of his true endowment should an agent share?

According to the best endowment response (26), agent i should declare that he is exposed to a risk he does not possess. Some of the endowments however may be of special and distinct type (such as exposure to specific financial positions or distinguishable insurance contracts or certain business revenues). Reporting exposure to them can be considered as signal of agent being more a risk seeker (speculator) than a hedger. As we have pointed out before, this kind of markets are in principle oligopolies and the strategy indicated by problem (25) may be against the general policy of the agent's firm. In such situations, where agent i is worried that this strategic behavior will deteriorate the conditions of future businesses with the other agents, he may alternatively consider the option to report as his endowment not any random variable but a positive percentage of his true endowment. In other words, he reports the direction of the randomness of his true risk exposure, but he chooses how much of it he is willing to share.

To emphasize the difference with problem (25), we hereafter use the notation $g_i(b; \mathcal{E}_{-i})$ instead of $G_i(b\mathcal{E}_i; \mathcal{E}_{-i})$, where the domain of the function g_i is set equal to interval $[0, \infty)$. In these situations, problem (25) is written as

$$\max_{b \in [0,\infty)} \{g_i(b; \mathcal{E}_{-i})\} \tag{27}$$

and the maximizer shall be called *best percentage response.* We deal with this restriction in the proposition below, the proof of which follows the lines of Proposition 5.

Proposition 6. *Suppose that $\mathcal{E}_i$ is not constant and the rest of the agents have reported endowments $\mathcal{E}_1, ..., \mathcal{E}_{i-1}, \mathcal{E}_{i+1}, ..., \mathcal{E}_n$. The best percentage response of agent i is*

$$b_i^* = 0 \vee \left(\frac{\gamma_i}{\gamma_i + \gamma} + \frac{\gamma^2}{\gamma_i^2 - \gamma^2} \rho(\mathcal{E}_i, \mathcal{E}_{-i}) \sqrt{\frac{\mathbb{V}\mathrm{ar}[\mathcal{E}_{-i}]}{\mathbb{V}\mathrm{ar}[\mathcal{E}_i]}} \right) \tag{28}$$

for each $i \in \{1, ..., n\}$, where $\rho(.,.)$ is the correlation coefficient map.[10]

From (28) we notice the following:

---

[10] Also $x \vee y$ stands for $\max\{x, y\}$, for $x, y \in \mathbb{R}$.

(i) As agent's risk averse increases, the best percentage approaches one, i.e., $\lim_{\gamma_i \to \infty} b_i^* = 1$, no matter the correlations of the endowments or their variances. This is consistent with the fact that the speculation attitude that characterizes the strategic behavior vanishes as the risk aversion increases. On the other hand, this attitude is more intense when γ_i goes to zero (i.e., when agent is risk neutral). In the limit we have

$$\lim_{\gamma_i \to 0} b_i^* = \begin{cases} 0, & \rho\left(\mathcal{E}_i, \mathcal{E}_{-i}\right) < 0; \\ \frac{1}{2}, & \rho\left(\mathcal{E}_i, \mathcal{E}_{-i}\right) = 0; \\ +\infty, & \rho\left(\mathcal{E}_i, \mathcal{E}_{-i}\right) > 0. \end{cases}$$

(ii) The best percentage response of agent i is an increasing function of $\rho\left(\mathcal{E}_{-i}, \mathcal{E}_i\right)$. Given his risk aversion coefficient, agent i is going to take a speculation only position (no short selling any of his endowment) if the correlation $\rho\left(\mathcal{E}_{-i}, \mathcal{E}_i\right)$ is sufficiently negative. This fact is at first glance surprising since negative endowment correlation implies good hedging opportunities. Since, agent i knows that there is an intense hedging demand, he prefers to act as buyer and enjoys the low prices of the endowments the other agents want to sell. In addition, long position in $\mathcal{E}_{-i}$ implies that he still achieves some hedging of this true risk exposure. The situation differs when $\rho\left(\mathcal{E}_{-i}, \mathcal{E}_i\right) > 0$. If this correlation is close enough to one, agent i reports overexposure on $\mathcal{E}_i$ which means that after the transaction he will be left with an exposure of negative $\mathcal{E}_i$. Taking into account the simultaneous long position on $\mathcal{E}_{-i}$, his total position will be of much less variance.

3.3 Which is the best demand on C that an agent should ask?

We now apply a similar agent's behavior in the case of the constrained risk sharing, where the agents share their risk exposures by trading at equilibrium a given vector of securities which differs than $\mathbf{E}$ meaning that the market remains incomplete. This market is influenced by an individual agent's strategic behavior only in the case where the number of the participating agents is low or when some of the agents' market power is strong. This is appropriate to the markets of structured financial products which function more than oligopolies rather than perfect competitions (where agents are in fact price-takes). By including such model extension we are able to see how an individual agent can *manipulate* the market price/allocation and how this situation is connected with the best endowment response.

We adapt the incomplete market model of a given vector of securities $\mathbf{C}$ whose equilibrium price/allocation is given by Definition 2 (see also Proposition 2). In these situations, each agent reports his demand function $Z_i(\mathbf{p})$ and the allocation of $\mathbf{C}$ is done at the price vector that clears out the market. Following the argument of the previous discussion, we consider agent i and suppose the he can exact the aggregate demand function of the rest of the agents. Note that under M-V preferences, agent's demand function is linear with slope equal to $-\frac{\mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}]}{2\gamma_i}$. This means that agent i extracts the demand functions of agent j only by getting his risk aversion coefficient and one value of the function $Z_j(\mathbf{p})$. Given this knowledge, agent i reveals a demand function that makes the market clear out and at the same time maximizes his expected utility after the equilibrium transaction. In particular, we ask: *which is the best equilibrium price for agent i?* As before, the word "*best*" refers to utility maximization. This problem is written as

$$\max_{\mathbf{p}\in\mathbb{R}^k}\phi_i(\mathbf{p};\sum_{j\neq i}Z_j(\mathbf{p})) \tag{29}$$

where

$$\phi_i(\mathbf{p};\sum_{j\neq i}Z_j(\mathbf{p}))=\mathbb{U}_i(\mathcal{E}_i-\sum_{j\neq i}Z_j(\mathbf{p})\cdot\mathbf{C})+\sum_{j\neq i}Z_j(\mathbf{p})\cdot\mathbf{p} \tag{30}$$

The maximizer of ϕ_i gives the equilibrium price that is most preferable for agent i, given the demand functions of the rest of the agents. In this oligopoly market, he can make the market equilibrate at this price by bid/ask the corresponding quantities of $\mathbf{C}$ or equivalently by reporting the appropriate demand function.

In case of M-V preferences, the calculation of this maximizer is straightforward due to the linearity of demand functions. Hence, we are able to see how the CAPM equilibrium prices change when an individual agent manipulates the market equilibrium by reporting the best-response demand function.

Proposition 7. *The equilibrium price of* $\mathbf{C}$ *that maximizes the utility of agent i given the aggregate demand function of the other agent* $\sum_{j\neq i}Z_j(\mathbf{p})$, *is*

$$\hat{\mathbf{p}}_i=\mathbb{E}[\mathbf{C}]-2\gamma\,\mathbb{C}\mathrm{ov}\left(\mathbf{C},\frac{\gamma_i}{\gamma_i+\gamma}\mathcal{E}_i+\frac{\gamma_i^2}{\gamma_i^2-\gamma^2}\mathcal{E}_{-i}\right). \tag{31}$$

We may rewrite problem (29) in terms of best demand function (this task is useful for the Nash equilibrium prices of $\mathbf{C}$, studied in the following section). Let first denote by $\mathcal{Z}_i$ the set of all demand functions for a given and fixed vector $\mathbf{C}$ of an agent with M-V preferences and risk aversion γ_i. Since, all these demand functions have a specific form given in (5), we can parameterize $\mathcal{Z}_i$, i.e., a function $d_i:\mathbb{R}^k\to\mathbb{R}^k$ belongs in $\mathcal{Z}_i$ if and only if there exists a vector $\mathbf{c}\in\mathbb{R}^k$ such that $d_i(\mathbf{p})=\left(\frac{\mathbb{E}[\mathbf{C}]-\mathbf{p}}{2\gamma_i}-\mathbf{c}\right)\cdot\mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}]$. In other words, we identify the M-V demand function with covariance vectors. Therefore, agent i can make the market equilibrate at price $\hat{\mathbf{p}}_i$ given in (31), by reporting the demand $\hat{Z}_i\in\mathcal{Z}_i$ such that

$$\hat{Z}_i(\hat{\mathbf{p}}_i)+\sum_{j\neq i}Z_j(\hat{\mathbf{p}}_i)=\mathbf{0}.$$

It follows that

$$\hat{Z}_i(\mathbf{p})=\left(\frac{\mathbb{E}[\mathbf{C}]-\mathbf{p}}{2\gamma_i}-\mathbb{C}\mathrm{ov}(\mathbf{C},B_i^*)\right)\mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}]. \tag{32}$$

where, B_i^* is given in (26). This means that the best endowment response of agent i is B_i^* for both the unconstrained and the constrained risk sharing market (for every tradeable securities $\mathbf{C}\in\mathbb{L}^2(\mathcal{F})$).

Therefore, the covariance part of the CAPM valuation is $\mathbb{C}\mathrm{ov}\left(\mathbf{C},\frac{\gamma_i}{\gamma_i+\gamma}\mathcal{E}_i+\frac{\gamma_i^2}{\gamma_i^2-\gamma^2}\mathcal{E}_{-i}\right)$, that is the effective aggregate endowment is not $\mathcal{E}$, and the factor of $\mathcal{E}_i$ is reduced by a percentage equal to $\frac{\gamma}{\gamma_i+\gamma}$, whereas the factor of $\mathcal{E}_{-i}$ increased by a percentage equal to $\frac{\gamma^2}{\gamma_i^2-\gamma^2}$ (e.g., for homogenous agents these percentages are -33% and $+33\%$ for $n=2$ and -25% and $+12.5\%$ for $n=3$ etc). Intuitively, by reporting less of his true endowment through his demand function, agent i increases the price of the securities that he is going to short and by increasing the effective endowment of the rest of the agents decreases the prices of the securities that he is going to long.

4 Nash Equilibria in Risk Sharing Games

If one agent applies a certain type of strategy in the aforementioned risk sharing markets, why not the other agents follow a similar behavior? As we have seen above, by submitting his best endowment response an agent can get a significant improvement of the utility he enjoys from these transactions. In the markets where the renegotiation is allowed, it is reasonable to suppose that all agents will follow this beneficial strategy and report the endowments (or demand functions) that maximizes their utilities given the reported endowments (or demands) of the rest of the agents. This sequel of responses can be thought as a modelling of the negotiation of the contract designing among the agents. This is a pure Nash type of game, where the agents' set of responses depends on the setting of the risk sharing market (e.g. problems (25) or (27))

The question that follows is whether this sequential negotiation has an equilibrium and how this equilibrium differs from the Pareto optimal one. Below, explicit answers are given in the cases where agents renegotiate the whole randomness of their endowments, the percentage of their true endowments and the price-allocation of a given vector of securities **C**.

4.1 Nash equilibrium in sharing of endowments

We first consider the case of optimal risk sharing rules that are the solutions of problems (6) or (7). However, we assume that each participant follows the strategic behavior indicated by problem (25). In other words, it is supposed that agents have agreed on the mechanism that produces the optimal sharing rules and the corresponding cash transferring and they negotiate their "shared-to-be" endowments. given the responses of the other agents, each one gives his best responses and the equilibrium occurs when this renegotiation ends. We shall call this equilibrium *Nash risk sharing equilibrium*, which definition is given below (note that this definition presupposes that the addiction costs and the time of this negotiation are negligible).

Definition 3. *We call a vector of random variables* $(B_1^*, ..., B_n^*) \in (\mathbb{L}^2(\mathcal{F}))^n$ *Nash risk sharing equilibrium if for each* $i \in \{1, ..., n\}$

$$G_i(B_i^*; (B_j^*)_{j\neq i}) \geq G_i(B; (B_j^*)_{j\neq i}) \tag{33}$$

for all $B \in \mathbb{L}^2(\mathcal{F})$.

The following theorem states the explicit form of this equilibrium under M-V preferences.

Theorem 1. *Let all agents follow the strategy indicated by* (25)*. Then there exists a unique (up to constants) Nash risk sharing equilibrium and for each* $i \in \{1, ..., n\}$ *the following statements hold:*

(i) The best endowment response of agent i at Nash equilibrium is given by

$$B_i^* = \frac{\gamma_i}{\gamma_i + \gamma_{-i}}\mathcal{E}_i + \left(\frac{\gamma_{-i}}{\gamma_i + \gamma_{-i}}\right)^2 \mathcal{B}^* \tag{34}$$

where $(\gamma_{-i})^{-1} = \sum\limits_{j\neq i} \frac{1}{\gamma_j}$ *and* $\mathcal{B}^*$ *is the aggregate shared risk,* $\mathcal{B}^* = \sum_{i=1}^n B_i^*$*, given by*

$$\mathcal{B}^* = \frac{\mathcal{E} - \gamma \sum_{i=1}^n \frac{\mathcal{E}_i}{\gamma_i}}{1 - \sum_{i=1}^n \frac{\gamma^2}{\gamma_i^2}} \tag{35}$$

(ii) The contract that agent i gets at the optimal sharing is

$$C_i^*(B_i^*) = \frac{\gamma_i - \gamma}{\gamma_i}\left(-\mathcal{E}_i + \frac{\gamma}{\gamma_i}\mathcal{B}^*\right) \tag{36}$$

Thanks to the explicit formulas of the equilibrium contracts, we are able to measure the inefficiency that this game implies.

Corollary 1. *The risk sharing inefficiency caused by agents' strategic behavior is given by*

$$\sum_{i=1}^{n} \mathbb{U}_i(\mathcal{E}_i + C_i^*) - \sum_{i=1}^{n} \mathbb{U}_i(\mathcal{E}_i + C_i(B_i^*)) = \sum_{i=1}^{n} \gamma_i \,\mathbb{V}\mathrm{ar}[\mathcal{E}_i - B_i^*] - \gamma \,\mathbb{V}\mathrm{ar}[\mathcal{E} - \mathcal{B}^*]. \tag{37}$$

Note that for all the non-trivial cases the inefficiency is strictly positive, since it equals to zero if and only if $\mathbb{V}\mathrm{ar}[\gamma_i\mathcal{E}_i - \gamma_j\mathcal{E}_j] = 0$, for each $i, j \in \{1, ..., n\}$, a condition that implies no transaction among the agents (agents are already at Pareto optimal condition).

In order to interpret better the findings of Theorem 1, we see thoroughly the simplified case of two agents, which is summarized and compared to the Pareto risk sharing in the following table (the considered position is of agent 1). The discussion that follows can well be applied in the cases where $n > 2$.

	Pareto Sharing	Nash Sharing
Aggregate shared endowment	$\mathcal{E}$	$\frac{\gamma_1\mathcal{E}_1+\gamma_2\mathcal{E}_2}{2\gamma}$
Reported endowment	$\mathcal{E}_1$	$\frac{2\gamma_1+\gamma_2}{2(\gamma_1+\gamma_2)}\mathcal{E}_1 + \frac{\gamma_2^2}{2\gamma_1(\gamma_1+\gamma_2)}\mathcal{E}_2$
Purchased contract	$\frac{\gamma_2\mathcal{E}_2-\gamma_1\mathcal{E}_1}{\gamma_1+\gamma_2}$	$\frac{1}{2}\frac{\gamma_2\mathcal{E}_2-\gamma_1\mathcal{E}_1}{\gamma_1+\gamma_2}$
Gain of utility from sharing	$\gamma_1 \,\mathbb{V}\mathrm{ar}\left[\frac{\gamma_1\mathcal{E}_1-\gamma_2\mathcal{E}_2}{\gamma_1+\gamma_2}\right]$	$\frac{\gamma_1+2\gamma_2}{4}\,\mathbb{V}\mathrm{ar}\left[\frac{\gamma_1\mathcal{E}_1-\gamma_2\mathcal{E}_2}{\gamma_1+\gamma_2}\right]$
Inefficiency	0	$\frac{1}{\gamma_1+\gamma_2}\,\mathbb{V}\mathrm{ar}\left[\frac{\gamma_1\mathcal{E}_1-\gamma_2\mathcal{E}_2}{2}\right]$

Table 1: Comparison of Pareto and Nash equilibrium when $n = 2$.

Without loss of generality we may assume that $\gamma_1 < \gamma_2$ (agent 1 is less risk averse). The first observation is that the aggregate shared endowment is different that the true one. In particular, the endowment of the risk averse agent that is actually shared is multiplied by a factor higher than one. On the other hand, only a part of the endowment of the agent with low risk aversion is shared. The contract that is designed at this (non-optimal) risk sharing setting is in fact the half of the optimal one, which means that the outcome of this renegotiation game is that the market losses half of its volume.

Furthermore, although the aggregate utility is lower in the case of Nash equilibrium, there exist situations where *some of the agents enjoy higher utility when the Nash-game is played*[11]. The factor that determines whether this happens is the agents' risk aversion levels. In case of two agents, agent 1 benefits from playing this sharing game if he is sufficiently less risk averse than agent 2 (when in particular $\gamma_1 < \frac{2}{3}\gamma_2$). It is clear that this type of negotiation game could be beneficial for agents with very low risk aversion. This is a potential problem of effectiveness of the risk sharing markets. Although the loss of the aggregate utility is always an outcome of the aforementioned negotiation procedure, the allocation of this loss is higher for more risk averse agents. This means that each agent would like to share risk with risk averse agents and avoid the ones with more risky attitudes. Eventually and for transactions where $\mathbb{V}\mathrm{ar}[\mathcal{E}_1 - \mathcal{E}_2]$ is relatively small, this trend will reduce the participants of this sharing market and hence its efficiency. In other words, the aforementioned market model suggests that transactions with low shared risk will tend to involve homogeneous only agents.

---

[11] Similar comparison of utility gain has been studied by Palomino (1996), where it is shown that there are cases where noise traders enjoy higher utility than the sophisticated ones under Nash equilibrium prices.

Another aspect of Theorem 1 is the interaction of agents' behaviors. More precisely, we get from (34) that the reported equilibrium endowment of agent i approaches his true endowment $\mathcal{E}_i$ as his risk aversion coefficient increases (theoretically up to infinity). On the other hand, the limit of B_i^* as γ_i goes to zero is unbounded. The interesting fact however is that when the risk aversion of agent 1 goes to zero, agent 2 behaves as he were very risk averse, that is the limit of B_2^* as $\gamma_1 \to 0$ equals to $\mathcal{E}_2$ independently on the value of γ_2. Similarly, the limit of B_2^* is unbounded as $\gamma_1 \to \infty$. We conclude that *very risk averse counterparty makes agents behave as risk neutral and vice versa.*

Note also, that the aggregate shared endowment is equal to the true one if and only if agents are homogeneous, i.e., when $\gamma_i = \gamma_j$, for all $i, j \in \{1, ..., n\}$ (all risk are shared, although not optimally).

Corollary 2. *$\mathcal{B}^* = \mathcal{E}$ if and only if agents are homogenous.*

In the special case of homogenous agents, the risk sharing inefficiency is equal to $\frac{1}{n^2}\left(\sum_{i=1}^n \mathbb{V}\mathrm{ar}[\mathcal{E}_i] - \frac{\mathbb{V}\mathrm{ar}[\mathcal{E}]}{n}\right)$ and shared equally among them (all agents suffer some utility loss after the negotiation). Furthermore, the best endowment response at equilibrium is given by $B_i^* = \frac{1}{n^2}\mathcal{E}_{-i} + \frac{n(n-1)+1}{n^2}\mathcal{E}_i$ and the contract that agent i gets is equal to $\frac{n-1}{n}C_i^*$, for each $i \in \{1, ..., n\}$. It also holds that the risk sharing inefficiency vanishes as the number of agents increases (provided that the agents' endowments are uniformly bounded in $\mathbb{L}^2(\mathcal{F})$). Under some additional mild assumptions, this result can be generalized even in the case of heterogeneous agents, as it is stated in the following proposition.

Proposition 8. *Consider a sequence of agents with random endowments $(\mathcal{E}_i)_{i\in\mathbb{N}}$ and risk aversion coefficients $(\gamma_i)_{i\in\mathbb{N}}$. If there exist constants M, c and C such that $||\mathcal{E}_i||_{\mathbb{L}^2(\mathcal{F})} \leq M$ and $c \leq \gamma_i \leq C$ for each $i \in \mathbb{N}$, the risk sharing inefficiency given in* (37) *goes to zero as $n \to \infty$.*

4.2 Nash equilibrium on reported percentages of true endowments

The arguments that lead to an equilibrium when agents follow a strategic behavior in risk sharing market can also be applied when agents renegotiate the percentage of their true endowments (problem (27)). Each agent's choice of endowment is restricted to whether he is going to share only a fraction of his true one or a multiple of it. As we have seen in Section 3, this best percentage response depends on the "shared-to-be" endowments of the rest of the agents (in fact on their sum). However, there is no reason why we should not consider all agents having the same strategic behavior. This presupposes that the renegotiation of the endowments is allowed in the designing of the optimal contracts and their prices. The main difference of this game theoretic sharing market model with the Nash endowment game is that agents do not renegotiate the randomness of their reported endowments, but only their sizes. The percentage of agents that equilibrate the market shall be called *Nash risk sharing percentage equilibrium*, the definition of which follows.

Definition 4. *We call a vector* $(b_1^*, ..., b_n^*) \in [0, \infty)^n$ *Nash risk sharing percentage equilibrium if for every agent* i

$$g_i\left(b_i^*; (b_j^*\mathcal{E}_j)_{j\neq i}\right) \geq g_i\left(b_i; (b_j^*\mathcal{E}_j)_{j\neq i}\right) \tag{38}$$

for every $b_i \geq 0$.

Thanks to Glicksburg-Fan-Debreu Theorem (see among others Chapter 1 of Fudenberg and Tirole (1991)) and the linearity of the best response function for positive values (see (28)), we are able to establish the existence and the uniqueness of this equilibrium, provided there is a bound on agents' percentage choices[12].

Proposition 9. *Suppose that the reported percentage of all agents is bounded from above by an upper bound* κ*. Then, there exists a unique Nash risk sharing percentage equilibrium.*

In the simplified case of $n = 2$, Nash risk sharing percentage equilibrium, (b_1^*, b_2^*), solves the equations

$$b_i^* = \left(0 \vee \left(\frac{\gamma_i}{\gamma_i + \gamma} + \frac{\gamma^2 b_{-i}^*}{\gamma_i^2 - \gamma^2}\rho(\mathcal{E}_i, \mathcal{E}_{-i})\sqrt{\frac{\mathbb{V}\mathrm{ar}[\mathcal{E}_{-i}]}{\mathbb{V}\mathrm{ar}[\mathcal{E}_i]}}\right)\right) \wedge \kappa, \quad \text{for } i = 1, 2. \tag{39}$$

Using (39) one can first show that as in the case of Theorem 1, as agent i becomes more risk averse $b_i^* \to 1$, meaning that he is not interested in the aforementioned negotiation. The surprising result is that even if the other agent has a fixed risk aversion coefficient, when $\gamma_{-i} \to \infty$ he behaves as being risk neutral. More precisely, we have the following limits for equilibrium percentages:

$$\lim_{\gamma_i \to \infty} b_{-i}^* = \lim_{\gamma_{-i} \to 0} b_{-i}^* = \begin{cases} 0, & \rho\left(\mathcal{E}_i, \mathcal{E}_{-i}\right) < 0; \\ \frac{1}{2}, & \rho\left(\mathcal{E}_i, \mathcal{E}_{-i}\right) = 0; \\ \kappa, & \rho\left(\mathcal{E}_i, \mathcal{E}_{-i}\right) > 0, \end{cases} \quad \text{and} \quad \lim_{\gamma_i \to \infty} b_i^* = \lim_{\gamma_i \to 0} b_{-i}^* = 1.$$

The above limits show how important is the risk level of each agent to the final sharing position of the other agents. An application that can be shown is that these limits imply that as one agent's risk aversion goes to zero the inefficiency of risk sharing goes to zero as well (the other agent reports his true endowment no matter his risk aversion). This dual behavior of the equilibrium percentage results in vanishing risk sharing inefficiency even if one of the agent risk aversion goes to infinity. We conclude that in this game, the risk sharing inefficiency vanishes as one of the agents risk aversion goes to zero or infinity.

In the special situation of homogeneous agents, the equilibrium percentage depends on riskness of agents' endowments and their correlation. Three different choices of the fraction $\frac{\mathbb{V}\mathrm{ar}[\mathcal{E}_2]}{\mathbb{V}\mathrm{ar}[\mathcal{E}_1]}$ are illustrated in Figures 1 and 2.

We observe the following:

---

[12] This bound restriction mitigates the magnitude of the shared endowments, however it is by no means restrictive when we consider practical applications.

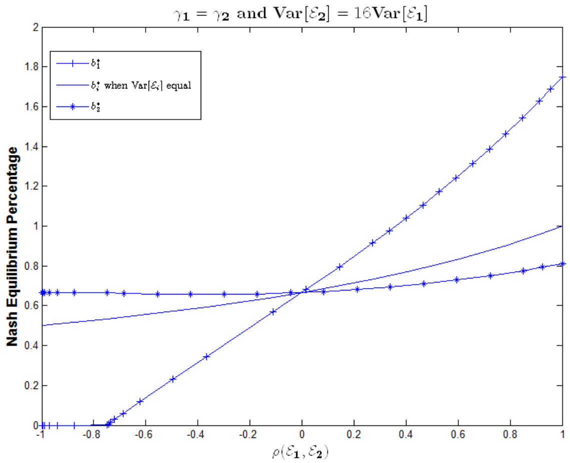

Figure 1: High risk of $\mathcal{E}_2$

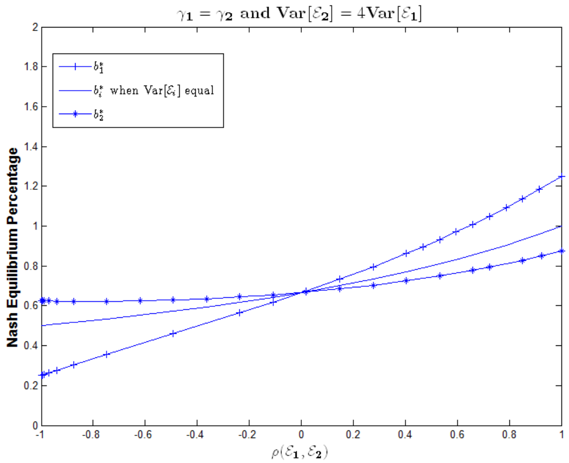

Figure 2: Low risk of $\mathcal{E}_2$

(i) The aggregate shared endowment is equal to $\mathcal{E}$ only in the trivial case where $\mathbb{V}\mathrm{ar}[\mathcal{E}_1] = \mathbb{V}\mathrm{ar}[\mathcal{E}_2]$ and $\rho(\mathcal{E}_1, \mathcal{E}_2) = 1$. In such a case however, the optimal risk sharing contract has constant payoff (no risk is transferred).

(ii) The agent with the riskier endowment (agent 2) reported lower percentage when $\rho(\mathcal{E}_1, \mathcal{E}_2)$ is positive (i.e., when sharing is a good hedging) and higher when $\rho(\mathcal{E}_1, \mathcal{E}_2)$ is negative (sharing is not a good hedging). One reason for this is that the large variance of endowment means lower equilibrium price of $\mathcal{E}_2$ and hence lower price of the contract that agent 2 is going to short at equilibrium. This price is even lower when endowments are positively correlated. However, when the correlation is negative, the price of $\mathcal{E}_2$ is higher and this together with the need for hedging induced by the high variance of $\mathcal{E}_2$ imply an increased b_2^*. This fact is more intense when the fraction $\frac{\mathbb{V}\mathrm{ar}[\mathcal{E}_2]}{\mathbb{V}\mathrm{ar}[\mathcal{E}_1]}$ is higher (Figure 1).

Similarly to the Nash risk sharing equilibrium (see discussion following Theorem 1), there are cases where the Nash percentage equilibrium is preferable by some particular agents. In Figures 3 and 4, we compare in different situations the gain of utility of agent 1 after the percentage renegotiation and when we have the Pareto risk sharing equilibrium.

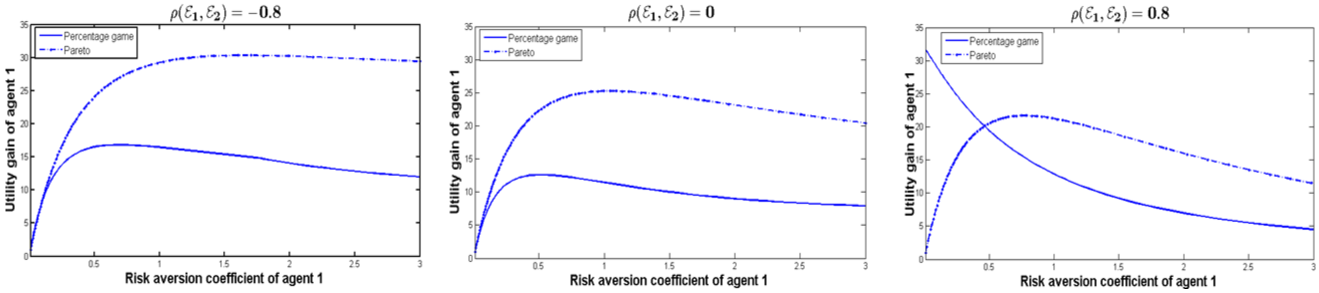

Figure 3: Utility gain of agent 1 when $\mathbb{E}[\mathcal{E}_i] = 0$, $\mathbb{V}\mathrm{ar}[\mathcal{E}_1] = \gamma_2 = 1$ and $\mathbb{V}\mathrm{ar}[\mathcal{E}_2] = 10\,\mathbb{V}\mathrm{ar}[\mathcal{E}_1]$.

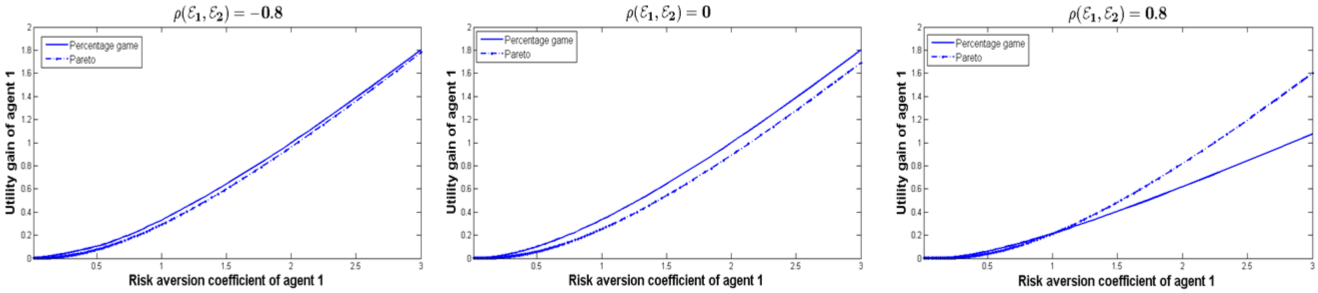

Figure 4: Utility gain of agent 1 when $\mathbb{E}[\mathcal{E}_i] = 0$, $\mathbb{V}\mathrm{ar}[\mathcal{E}_1] = \gamma_2 = 1$ and $\mathbb{V}\mathrm{ar}[\mathcal{E}_2] = \frac{1}{10}\,\mathbb{V}\mathrm{ar}[\mathcal{E}_1]$.

It is clear that agent 1 prefers a Nash equilibrium percentage game when: (i) his endowment is riskier and the endowments' correlation is not positive (i.e., risk sharing is a good hedging) and (ii) his risk aversion is low and endowments' correlation is positive and large (i.e., sharing is not a good hedging). When agent 1 has an increased need for hedging and sharing of endowments is a good hedging choice, playing a Nash-type of game is beneficial, providing that the risk aversion of agent 2 is not very low. If agent 2 is close to risk neutrality, the game is going to be more speculative something that is against the agent with higher hedging need. On the other hand, when his hedging need is low, he prefers playing the game when his risk aversion is very low (he is a speculator more than a hedger) and sharing does not provide a good hedging. In these situations, agent 2 reports only a fraction of his risky endowment and agent 1 a multiple of his low-risk endowment (see Figures 1 and 2). Summarizing these facts, we conclude that agents prefer this renegotiation game if they have risky portfolios and the sharing of endowment is a good hedging and when their portfolios are (relatively) not very risky and sharing is not a good hedging. In any case however, the gain of utility is increased when the sharing is done with an agent with high risk aversion.

4.3 The CAPM in oligopoly financial markets

The arguments of Nash equilibrium risk sharing can be applied even in the case of constrained risk sharing setting, i.e., a market of a given vector of securities $\mathbf{C} \in (\mathbb{L}^2(\mathcal{F}))^k$. As we have seen in subsection 2.2, the equilibrium price-allocation of $\mathbf{C}$ occurs at the point where agents' demand functions sum up to zero. In markets where the number of participating agents is small (or few particular agents have strong market power), the actions of each individual one should clearly affect the market equilibrium. A way an agent manipulates the market equilibrium is modelled by the optimization problem (29), where given the aggregate demand function of the rest of the agents, an agent drives the market to his "preferable" equilibrium price by reporting a different demand for $\mathbf{C}$ than his true one. However, in the market situations where the renegotiation of the prices of $\mathbf{C}$ is allowed, all participants (or at least the ones that have sufficient market power) would follow the same strategic behavior and change their demand schedule in the way indicated by (29). As in the previously analyzed market models, the Nash-type of equilibrium occurs when this renegotiation reaches a fixed point.

From Proposition 7 and the related discussion that follows, we get that the demand function of agent i which equilibrates the market at his preferable price, depends on the aggregate demand function of the other agents (see (31)). Therefore, the subjective function of agent i is $\phi_i(\mathbf{p}; \sum_{j\neq i} \tilde{Z}_j)$, where $\tilde{Z}_j \in \mathcal{Z}_j$ is the reported demand function of agent j, for $j \neq i$. The negotiation setting is similar to the one introduced in the seminal work of Kyle (1989) and it is described as follows: Agents negotiate the *one-shot* trading of $\mathbf{C}$ by submitting prices at which they are willing to long or short each security C_u, $u \in \{1, ..., k\}$. Under M-V preferences, agent i can induce the whole demand schedule of the the rest of the agents only from one vector of orders on $\mathbf{C}$ and the aggregate risk aversion γ_{-i} (practically he needs one more value of the aggregate demand to infer the parameter γ_{-i}). Let us take the position of agent 1, who gets the bid/ask prices from the rest of the agents. Then, he follows the strategic behavior indicated by (31) and asks the demand function $\hat{Z}_1$ that equilibrates the market at the price $\hat{\mathbf{p}}_1$. This is the price of the actual transaction if the rest of the agents do not change their submitted demands. However, if they do so, the equilibrium will be adjusted analogously. For example, agent 2 will modify his demand to $\tilde{Z}_2$ in order to make the equilibrium price equal to the maximizer of his optimization problem $\max\{\phi_2(\mathbf{p}; \hat{Z}_1 + \sum_{j=3}^n \tilde{Z}_j)\}$. This demand function will be taken into account by agent 3 who is going to follow a similar demand adjustment. The raised question is whether this sequel of price negotiation reaches an equilibrium point. We set $\mathcal{Z} = \mathcal{Z}_1 \times ... \times \mathcal{Z}_n$ and give the corresponding equilibrium of this Nash-type game below.

Definition 5. *The pair* $(\hat{\mathbf{p}}, \hat{\mathbf{Z}}) \in \mathbb{R}^k \times \mathcal{Z}$ *is a Nash equilibrium price-demand of vector of securities* $\mathbf{C}$ *if*

(i) $\sum_{i=1}^n \hat{Z}_i(\hat{\mathbf{p}}_i) = 0$ *(the demands clear out at price* $\hat{\mathbf{p}}$*) and*

(ii) For each $i \in \{1, ..., n\}$

$$\phi_i(\hat{\mathbf{p}}; \sum_{j\neq i} \hat{Z}_j) \geq \phi_i(\mathbf{p}; \sum_{j\neq i} \hat{Z}_j), \quad \textit{for every} \quad \mathbf{p} \in \mathbb{R}^k$$

($\hat{\mathbf{p}}$ *is the best price of each agent given the demand of the rest of the agents).*

The vector $(\hat{Z}_1(\hat{\mathbf{p}}), ..., \hat{Z}_n(\hat{\mathbf{p}}))$ *is called Nash equilibrium allocation of* $\mathbf{C}$ *at price* $\hat{\mathbf{p}}$.

Under M-V preferences, this equilibrium is a *variation of the CAPM* in markets where one of the main assumptions of this model, that all participants in the market are price-takers, is withdrawn. This variation is an essential part of the modelling of the markets of the securities that consist of a few number of agents and the transaction is an outcome of a sequel of negotiations on the price and the volume of the transaction.

Theorem 2. *The unique Nash equilibrium price of a vector of securities* $\mathbf{C}$ *is given by*

$$\hat{\mathbf{p}} = \mathbb{E}[\mathbf{C}] - 2\gamma\, \mathbb{C}\mathrm{ov}(\mathbf{C}, \mathcal{B}^*) \tag{40}$$

where $\mathcal{B}^*$ *is given in* (35) *and the Nash equilibrium demands* $\hat{Z} = (\hat{Z}_1, ..., \hat{Z}_n) \in \mathcal{Z}$ *have the form*

$$\hat{Z}_i(\mathbf{p}) = \left(\frac{\mathbb{E}[\mathbf{C}] - \mathbf{p}}{2\gamma_i} - \mathbb{C}\mathrm{ov}(\mathbf{C}, B_i^*) \right) \mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}] \tag{41}$$

for every $i \in \{1, ..., n\}$, *where* B_i^* *is given in* (34). *Also, the Nash equilibrium allocation at price* $\hat{\mathbf{p}}$ *is*

$$\hat{Z}_i(\hat{\mathbf{p}}) = \mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*(B_i^*)) \cdot \mathbb{V}\mathrm{ar}^{-1}[\mathbf{C}] \tag{42}$$

where $C_i^*(B_i^*)$ *is given in* (36).

Corollary 3. *The Nash equilibrium prices coincide with the CAPM equilibrium prices if and only if agents are homogeneous.*

This Nash-type game among agents results in a change of the covariance value of the security equilibrium prices. In fact, the induced covariance is the one between the vector of securities payoffs **C** and the payoff of the Nash equilibrium aggregate endowment (see Theorem 1) instead of the true aggregate endowment $\mathcal{E}$. This gives a clear connection between the Nash negotiation in the constrained and the unconstrained market. In words, when heterogeneous agents follow strategic behavior in sharing their risks, the effective market portfolio, i.e., the aggregate shared endowment differs than the true one and is the same for both the optimal risk sharing and the constrained risk sharing markets. Hence, *in any case where renegotiation is allowed* $\mathcal{E}$ *should be replaced by* $\mathcal{B}^*$.

We may compare the above equilibrium with the excess return version of the CAPM (see among others Chapter 3 of Magill and Quinzii (1996)). For this, we assume that $\mathcal{E}_i$ belongs to the span of the traded securities **C**, that is for every $i \in \{1, ..., n\}$, $\exists \mathbf{b}^i \in \mathbb{R}^k$, such that $\mathcal{E}_i = \sum_{j=1}^k b_j^i C_j$. Then, for every payoff X which belongs to the span of **C**, its equilibrium required expected excess return (denoted by R_X) satisfies

$$\mathbb{E}[R_X] = \frac{\mathbb{C}\mathrm{ov}(R_X, R_{\mathcal{B}^*})}{\mathbb{V}\mathrm{ar}[R_{\mathcal{B}^*}]}\mathbb{E}[R_{\mathcal{B}^*}]. \tag{43}$$

Note that $\mathcal{E}$ equals $\mathcal{B}^*$ and hence the required expectation of any market position remains unaffected by the agents' strategic behavior only in the special case of homogeneous agents.

Although the Nash equilibrium prices coincide with the CAPM prices when agents are homogeneous, the equilibrium allocations differ. We calculate that the equilibrium volume is reduced for each security and in particular $\hat{Z}_i(\hat{\mathbf{p}}) = \frac{n-1}{n} Z_i(\mathbf{p}^*)$, for each i. This implies (see Proposition 3) that for each individual agent the gain of utility at Nash equilibrium transaction on **C** is decreased by the factor $\frac{n^2-1}{n^2}$, when compared to the Pareto equilibrium transaction on **C**. Hence, for homogeneous agents the renegotiation of the securities prices in the aforementioned setting results in a less utility for each of the agents even though the prices are the same.

The situation is different when agents are heterogeneous. As in Theorem 1 and Proposition 9, there are cases where some agents gain more utility on the Nash equilibrium transaction of **C**. For this, consider the simplified case of $n = 2$, $k = 1$ and $\mathbb{V}\mathrm{ar}[C] = 1$. Then, we calculate that

$$\mathbb{U}_1(\mathcal{E}_1 + \hat{Z}_1(\hat{\mathbf{p}})C - \hat{Z}_1(\hat{\mathbf{p}})\hat{\mathbf{p}}) = \mathbb{U}_1(\mathcal{E}_1 + Z_1^*(\mathbf{p}^*)C - Z_1^*(\mathbf{p}^*)\mathbf{p}^*) + \left(\gamma_2 - \frac{\gamma_1}{4} + \gamma_1 \frac{\mathbb{C}\mathrm{ov}(C, \mathcal{E}_1)}{\mathbb{C}\mathrm{ov}(C, C_1^*)}\right) \mathbb{C}\mathrm{ov}^2(C, C_1^*).$$

The above equation implies that agent 1 benefits from Nash equilibrium when for example agent 2 has sufficiently high risk averse, $\mathbb{C}\mathrm{ov}(C, \mathcal{E}_1) > 0$ (which means that agent 1 wants to go short on C) and $\mathbb{C}\mathrm{ov}(C, C_1^*) > 0$ (which implies that agent 2 wants to take larger short position on C). We can repeat this argument by changing the signs of the covariances and conclude that agent 1 benefits from Nash equilibrium when he wants to go long at C, but agent 2 asks for a larger long position. We summarize these findings in the following corollary.

Corollary 4. *When $n = 2$, the utility gain of agent 1 is higher at the Nash equilibrium transaction of a vector of securities $\mathbf{C}$ if agent 2 is more risk averse and wants to take a position on $\mathbf{C}$ of the same direction as agent 1, but larger.*

Furthermore, comparison of prices (12) and (40) gives the exact measure and the direction of the *price pressure* that agents' strategic behavior creates on securities in $\mathbf{C}$. For each $j \in \{1, ..., k\}$, we have that

$$p_j^* < \hat{p}_j \quad \text{if and only if} \quad \mathbb{C}\text{ov}(C_j, \mathcal{B}^*) < \mathbb{C}\text{ov}(C_j, \mathcal{E}),$$

and $\mathbb{C}\text{ov}(C_j, \mathcal{E} - \mathcal{B}^*)$ can be considered as the measure of the price pressure that is created to security C_j by the strategic game played by the participating agents. In particular, the game causes upward price pressure if $\mathbb{C}\text{ov}(C_j, \mathcal{E} - \mathcal{B}^*) > 0$ and negative price pressure if $\mathbb{C}\text{ov}(C_j, \mathcal{E} - \mathcal{B}^*) < 0$. For example in the case $n = 2$, $\mathbb{C}\text{ov}(C_j, \mathcal{E} - \mathcal{B}^*)$ equals to $\frac{\gamma_2 - \gamma_1}{2\gamma_1\gamma_2}\mathbb{C}\text{ov}(C_j, \gamma_1\mathcal{E}_1 - \gamma_2\mathcal{E}_2)$, which is positive when agent 2 is more concerned about risk and he wants to take long position at equilibrium[13]. On the other hand, the Nash game causes a negative pressure on the price of asset C_j if the more risk averse agent wants to take a short position on it (which is good news for the low risk averse agent who takes the opposite position). Therefore, when (relatively few) agents negotiate an one-shot transaction of a bundle of financial securities, there is a price pressure caused by their strategic behavior which is in favor (in terms of utility gain) of low risk averse agents.[14] As in the case of unconstrained risk sharing, agents have a motive to seek for more risk averse agents in the transaction of securities in $\mathbf{C}$ since trading with them will make the prices move for their part (being higher when they short and lower when then long). This creates a potential formation of sub-group market of $\mathbf{C}$ involving homogenous only agents.

Finally, as in the case of Proposition 8, when the number of agents goes to infinity, the differences $\mathbf{p}^*(n) - \hat{\mathbf{p}}(n)$ and $\mathbf{a}_i^*(n) - \hat{\mathbf{a}}_i(n)$ vanish (where the indication (n) refers to the market of n agents). This is stated in the following proposition.

Proposition 10. *Consider a sequence of agents with random endowments $(\mathcal{E}_i)_{i\in\mathbb{N}}$ and risk aversion coefficients $(\gamma_i)_{i\in\mathbb{N}}$. If there exist constants M, c and C such that $||\mathcal{E}_i||_{\mathbb{L}^2(\mathcal{F})} \leq M$ and $c \leq \gamma_i \leq C$ for each $i \in \mathbb{N}$, then as $n \to \infty$*

---

[13] Recall from equation (13) that the allocation of agent 2 at Pareto equilibrium is $\mathbb{C}\text{ov}(\mathbf{C}, \frac{\gamma_1\mathcal{E}_1 - \gamma_2\mathcal{E}_2}{\gamma_1 + \gamma_2}) \cdot \mathbb{V}\text{ar}^{-1}[\mathbf{C}]$.

[14] As the aggregate utility is concerned, its decrease caused by the agents' strategic behavior is less (more) when agents are more (less) risk averse. For this, we calculate that the aggregate decrease in utility that is caused by the agents' strategic behavior, that is $\sum_{i=1}^n \mathbb{U}_i(\mathcal{E}_i + Z_i(\mathbf{p}^*) \cdot \mathbf{C}) - \sum_{i=1}^n \mathbb{U}_i(\mathcal{E}_i + \hat{Z}_i(\hat{\mathbf{p}}) \cdot \mathbf{C})$ equals to

$$\sum_{i=1}^n \gamma_i(\hat{Z}_i(\hat{\mathbf{p}}) - Z_i(\mathbf{p}^*)) \cdot \Big(\mathbb{V}\text{ar}[\mathbf{C}] \cdot (\hat{Z}_i(\hat{\mathbf{p}}) + Z_i(\mathbf{p}^*))' + 2\,\mathbb{C}\text{ov}(\mathcal{E}_i, \mathbf{C})\Big).$$

It is then easily proved that for each agent i the term $\gamma_i\hat{Z}_i(\hat{\mathbf{p}} - Z_i(\mathbf{p}^*)) \cdot \Big(\mathbb{V}\text{ar}[\mathbf{C}] \cdot (\hat{Z}_i(\hat{\mathbf{p}}) + Z_i(\mathbf{p}^*))' + 2\,\mathbb{C}\text{ov}(\mathcal{E}_i, \mathbf{C})\Big)$ goes to zero as γ_i goes to infinity, whereas its limit as γ_i goes to zero is unbounded.

(i) $||\mathbf{p}^*(n) - \hat{\mathbf{p}}(n)|| \to 0$ *and*

(ii) $||\mathbf{a}_i^*(n) - \hat{\mathbf{a}}_i(n)|| \to 0$*, for each* $i \in \mathbb{N}$.

5 Conclusion

This article provides an integrated theoretical model of the *risk sharing inefficiency* and the *mispricing of OTC traded securities*, that is based on the agents' strategic behavior regarding the risk they share. In the sections above, we introduce a risk sharing and a security pricing setting in which agents negotiate the risk that are going to share and the demand on given securities that are going to ask. We define the associate equilibria in both settings and under mean-variance preferences we extensively analyze and compare them.

First, we model the strategic behavior of an individual agent i in (optimal) risk sharing markets by asking *how much risk he should share* given the aggregate endowment of the other agents, (i.e., the random variable $\mathcal{E}_{-i}$). If his criterion is the maximization of his mean-variance utility, the best endowment response is to *share only a fraction of his true endowment*, $\mathcal{E}_i$, and to report that he is also exposed to a position proportional to $\mathcal{E}_{-i}$. If there are exogenous factors that restrict the best response to a percentage of $\mathcal{E}_i$, it is shown that the best percentage response is an increasing function of $\rho(\mathcal{E}_i, \mathcal{E}_{-i})$. The differences between both of these responses and $\mathcal{E}_i$ increase as the agent's risk aversion coefficient decreases.

The question that follows is whether and how the market reaches an equilibrium point when all the participants apply the same strategic behavior. We introduce an abstract definition of this Nash equilibrium and state its existence and characterization in Theorem 1. In particular, it is shown that the aggregate shared risk is equal to the true aggregate one if and only if agents are homogeneous. Even in this case however, the risk allocation is not efficient and the transaction volume is lower. We then define as risk sharing inefficiency the difference between the aggregate utility under the optimal risk sharing rule and the aggregate utility under the Nash equilibrium allocation. This inefficiency is strictly positive for every non-trivial situation and goes to zero when agents' risk aversion or the number of agents go to infinity.

The comparison of the Pareto (welfare optimal) equilibrium with the Nash equilibrium gives that agent with *sufficiently low risk aversion gets more utility in Nash transaction.* Furthermore, there exists a clear interaction of behaviors among agent in the sense that the ones with very low risk averse make the other agents behave as they were very risk averse and vise versa. An analogous situation occurs when agents negotiate the percentages of their true endowments that are going to share. In particular, the Nash percentage equilibrium game is beneficial for the low risk averse agents who have risky portfolios and the sharing of endowments is a good hedging or whose portfolios are (relatively) not very risky and sharing is not a good hedging. In any case, agents who aim to reduce their risk should look for counterparties of high risk aversion and negatively correlated endowments. Transactions that involve endowments of positive correlation, will eventually include homogenous only agents.

Similar strategies can be applied to the situations where agents trade a given vector of securities. In such cases, it is supposed that an agent *drives the market equilibrium prices* to the ones that maximize his quadratic utility by asking the appropriate demand schedule. It is shown that this so-called best demand response coincides with the demand function that corresponds to the best endowment response. When the same strategy is followed by all agents and the one-shot transaction allows a sequel of price-allocation negotiations, the equilibrium will be one of Nash type. We establish the exact definition and we provide its existence and uniqueness in Theorem 2. This equilibrium security prices can be thought as a game theoretic *variation of the CAPM* which is more appropriate in *oligopoly security markets.* This structure leaves the equilibrium prices unchanged only in the special case of homogeneous agents (although even in this case the volume of the equilibrium transactions and the induced agents' utility gains are reduced). When agents are heterogeneous, their strategic behavior may change the equilibrium prices heavily (e.g., high prices occur when risk averse agents have a very intense hedging need). Similarly to the previous case, the agents that benefit when such a game is played are the ones with low risk aversion and for whom the trading of given securities is not a very good hedging. As expected, Nash equilibrium prices converge to the Pareto ones when the number of agents increases to infinity.

Appendix A

Proof of Proposition 1

We have that for every $\mathbf{C} = (C_1, ..., C_n) \in \mathcal{A}$

$$\sum_{i=1}^{n} \mathbb{U}_i(\mathcal{E}_i + C_i) = \sum_{i=1}^{n} \mathbb{E}[\mathcal{E}_i] - \sum_{i=1}^{n} \gamma_i \, \mathbb{V}\mathrm{ar}[C_i + \mathcal{E}_i].$$

Hence, it is enough to find $\mathbf{C}^* \in \left(\mathbb{L}^2(\mathcal{F})\right)^n$ that minimizes the sum $\sum_{i=1}^{n} \gamma_i \, \mathbb{V}\mathrm{ar}[C_i + \mathcal{E}_i]$. Note the for each $i \in \{1, ..., n\}$,

$$C_i^* + \mathcal{E}_i = \frac{\gamma}{\gamma_i} \mathcal{E}$$

and

$$\gamma_i \, \mathbb{V}\mathrm{ar}[C_i^* + \mathcal{E}_i] = \frac{\gamma^2}{\gamma_i} \, \mathbb{V}\mathrm{ar}[\mathcal{E}],$$

where we recall that $\mathcal{E} = \sum_{i=1}^{n} \mathcal{E}_i$. Therefore,

$$\sum_{i=1}^{n} \gamma_i \, \mathbb{V}\mathrm{ar}[C_i^* + \mathcal{E}_i] = \sum_{i=1}^{n} \frac{\gamma^2}{\gamma_i} \, \mathbb{V}\mathrm{ar}[\mathcal{E}_i] = \gamma \, \mathbb{V}\mathrm{ar}[\mathcal{E}].$$

It is then enough to show that

$$\sum_{i=1}^{n} \gamma_i \, \mathbb{V}\mathrm{ar}[C_i + \mathcal{E}_i] \geq \gamma \, \mathbb{V}\mathrm{ar}[\mathcal{E}], \quad \text{for every } \mathbf{C} \in \mathcal{A}. \tag{44}$$

or equivalently

$$\sum_{i=1}^{n} \gamma \gamma_i \, \mathbb{V}\mathrm{ar}[C_i + \mathcal{E}_i] \geq \gamma^2 \, \mathbb{V}\mathrm{ar}[\mathcal{E}], \quad \text{for every } \mathbf{C} \in \mathcal{A}. \tag{45}$$

The left hand side of (45) equals to

$$\sum_{i=1}^{n} \frac{\gamma}{\gamma_i} \gamma_i^2 \, \mathbb{V}\text{ar}[C_i + \mathcal{E}_i] = \sum_{i=1}^{n} \frac{\gamma}{\gamma_i} \, \mathbb{V}\text{ar}[\gamma_i(C_i + \mathcal{E}_i)]$$

and inequality (45) follows by the convexity of $\mathbb{V}\text{ar}[\cdot]$ and the fact that $\sum_{i=1}^{n} C_i = 0$.

The last part of the proposition follows directly.

Proof of Proposition 5

We fix vector $(\mathcal{E}_1, ..., \mathcal{E}_{i-1}, \mathcal{E}_{i+1}, ..., \mathcal{E}_n) \in (\mathbb{L}^2(\mathcal{F}))^{n-1}$ and from (24) (with a slight abuse of notation) we get that

$$\begin{aligned} G_i(B) \;=\;& \mathbb{E}[\mathcal{E}_i] - \frac{\gamma^2}{\gamma_i} \, \mathbb{V}\text{ar}[\mathcal{E}] - \frac{(\gamma_i - \gamma)^2}{\gamma_i} \, \mathbb{V}\text{ar}[\mathcal{E}_i - B] - \frac{2\gamma(\gamma_i - \gamma)}{\gamma_i} \left(\mathbb{C}\text{ov}(\mathcal{E}, \mathcal{E}_i - B) + \mathbb{V}\text{ar}[B]\right) \\ &+ \frac{2\gamma(2\gamma - \gamma_i)}{\gamma_i} \, \mathbb{C}\text{ov}(B, \mathcal{E} - \mathcal{E}_i). \end{aligned} \tag{46}$$

Hence, in order to solve problem (25), it is enough to find $B \in \mathbb{L}^2(\mathcal{F})$ that minimizes

$$\frac{\gamma_i - \gamma}{2\gamma} \, \mathbb{V}\text{ar}[\mathcal{E}_i - B] + \mathbb{C}\text{ov}(\mathcal{E}, \mathcal{E}_i - B) + \mathbb{V}\text{ar}[B] + \mathbb{C}\text{ov}(B, \mathcal{E} - \mathcal{E}_i) \left(1 - \frac{\gamma}{\gamma_i - \gamma}\right).$$

Since the above quantity is constant invariant, we may consider for now that $\mathbb{E}[B] = 0$. Thus, we want to minimize function $W_i : \mathbb{L}^2(\mathcal{F}) \to \mathbb{R}$ defined by

$$W_i(B) = \mathbb{E}\left[\frac{\gamma_i - \gamma}{2\gamma}(\mathcal{E}_i - B)^2 + \mathcal{E}(\mathcal{E}_i - B) + B^2 + \left(1 - \frac{\gamma}{\gamma_i - \gamma}\right) B(\mathcal{E} - \mathcal{E}_i)\right].$$

The minimum of $W_i(\cdot)$ can be obtained through its *Fréchet derivative*. For this, we first show that the Fréchet derivative of $W_i(\cdot)$ at $B \in \mathbb{L}^2(\mathcal{F})$ (denoted by $D_{W_i(B)}$) is given by

$$D_{W_i(B)}[X] = \mathbb{E}\left[\left(\frac{\gamma_i + \gamma}{\gamma} B - \frac{\gamma_i - \gamma}{\gamma} \mathcal{E}_i - \mathcal{E} + \left(1 - \frac{\gamma}{\gamma_i - \gamma}\right)(\mathcal{E} - \mathcal{E}_i)\right) X\right],$$

for every $X \in \mathbb{L}^2(\mathcal{F})$. In order to prove this statement, it is enough to get the following limit

$$\frac{|W_i(B + X) - W_i(B) - D_{W_i(B)}[X]|}{||X||_{\mathbb{L}^2(\mathcal{F})}} \longrightarrow 0 \tag{47}$$

as $||X||_{\mathbb{L}^2(\mathcal{F})} \to 0$. Indeed,

$$\frac{|W_i(B + X) - W_i(B) - D_{W_i(B)}[X]|}{||X||_{\mathbb{L}^2}} = \left(\frac{\gamma_i + \gamma}{2\gamma}\right) \frac{|\mathbb{E}\left[X^2\right]|}{||X||_{\mathbb{L}^2}} = \left(\frac{\gamma_i + \gamma}{2\gamma}\right) ||X||_{\mathbb{L}^2} \longrightarrow 0.$$

Note that function $W_i(\cdot)$ is strictly convex in $\mathbb{L}^2(\mathcal{F})$ and hence, if there exists $B^* \in \mathbb{L}^2(\mathcal{F})$ such that $D_{W_i(B^*)}[X] = 0$ for each $X \in \mathbb{L}^2(\mathcal{F})$, then B^* is the unique (in the class of $\mathbb{L}^2(\mathcal{F})$ with expectation equal to zero) minimizer of $W_i(\cdot)$. Clearly, for B_i^* given in (26), $D_{W_i(B_i^*)}[X] = 0$ for every $X \in \mathbb{L}^2(\mathcal{F})$ which makes B_i^* the best response of agent i.

Proof of Theorem 1

From Proposition 5 and the FOCs for the Nash equilibrium, we get that Nash equilibria are the solutions $(B_1^*, ..., B_n^*) \in (\mathbb{L}^2(\mathcal{F}))^n$ of the following system of n linear equations

$$\begin{aligned} B_1^* &= \frac{\gamma_1}{\gamma_1+\gamma}\mathcal{E}_1 + \frac{\gamma^2}{\gamma_1^2-\gamma^2}\sum_{j\neq 1}^{n} B_j^* \\ B_2^* &= \frac{\gamma_2}{\gamma_2+\gamma}\mathcal{E}_2 + \frac{\gamma^2}{\gamma_2^2-\gamma^2}\sum_{j\neq 2}^{n} B_j^* \\ &\vdots \\ B_n^* &= \frac{\gamma_n}{\gamma_n+\gamma}\mathcal{E}_n + \frac{\gamma^2}{\gamma_n^2-\gamma^2}\sum_{j=1}^{n-1} B_j^* \end{aligned} \tag{48}$$

We fix $\omega \in \Omega$ and we are looking for $\mathbf{B} = (B_1, ..., B_n)$ which solves the above linear system. For each $i \in \{1, ..., n\}$, we have that $B_i^* = \frac{\gamma_i}{\gamma_i+\gamma}\mathcal{E}_i + \frac{\gamma^2}{\gamma_i^2-\gamma^2}\sum_{j=1}^n B_j^* - \frac{\gamma^2}{\gamma_i^2-\gamma^2}B_i^*$ which gives (34) and (35). Since $B_i^*(\omega)$ is a linear combination of $\mathcal{E}_1(\omega), ..., \mathcal{E}_n(\omega)$, $B_i^* : \Omega \longrightarrow \mathbb{R}$ is a $\mathcal{F}$-measurable and in particular it belongs in $\mathbb{L}^2(\mathcal{F})$.

Finally, it is left to observe that if $\mathbf{B}^* = (B_1^*, ..., B_n^*)$ is a Nash equilibrium, every vector of the form $\mathbf{B}^* + \mathbf{c}$, for $\mathbf{c} \in \mathbb{R}^n$ is also a Nash equilibrium, since it satisfies (33). The fact that this form of Nash equilibria is unique follows from the strict convexity of $G_i(\cdot)$. Equation (36) follows by straightforward calculations.

Proof of Proposition 8

We assume without loss of generality that $\mathbb{E}[\mathcal{E}_i] = 0$ for each $i \in \mathbb{N}$. It is enough to show that under the imposed assumptions the first term in (37), i.e., the sum $\sum_{i=1}^n \gamma_i \mathbb{V}\mathrm{ar}[\mathcal{E}_i - B_i^*]$ vanishes, as n goes to infinity. We fix $n \in \mathbb{N}$ and for an arbitrarily chosen $i \in \{1, ..., n\}$ we have

$$||\mathcal{E}_i - B_i^*||^2 = \left(\frac{\gamma_{-i}}{\gamma_i+\gamma_{-i}}\right)^2 ||\mathcal{E}_i||^2 + \left(\frac{\gamma_{-i}}{\gamma_i+\gamma_{-i}}\right)^4 ||\mathcal{B}^*(n)|| - 2\left(\frac{\gamma_{-i}}{\gamma_i+\gamma_{-i}}\right)^3 \langle \mathcal{E}_i, \mathcal{B}^*(n)\rangle, \tag{49}$$

where $(\gamma_{-i})^{-1} = \sum_{j\neq i}^n \frac{1}{\gamma_j}$, $\mathcal{B}^*(n)$ is the aggregated reported endowment of the n first agents, all mentioned norms are the $\mathbb{L}^2(\mathcal{F})$-norms and $\langle \cdot, \cdot \rangle$ is the associated inner product.

$$\begin{aligned} \sum_{i=1}^n \gamma_i \left(\frac{\gamma_{-i}}{\gamma_i+\gamma_{-i}}\right)^2 ||\mathcal{E}_i||^2 &\leq MC\sum_{i=1}^n \left(\frac{\gamma_{-i}}{\gamma_i+\gamma_{-i}}\right)^2 \\ &\leq \frac{MC^3}{(n-1)^2}\sum_{i=1}^n \frac{1}{(\gamma_i+\gamma_{-i})^2} \\ &\leq \frac{MC^3}{(n-1)^2}\frac{n(n-1)^2}{((n-1)c+C)^2} \end{aligned}$$

which goes to zero as $n \to \infty$. Also,

$$\begin{aligned} ||\mathcal{B}^*(n)||^2 &= \frac{1}{1-\sum_{i=1}^n\left(\frac{\gamma(n)}{\gamma_i}\right)^2}\left(||\mathcal{E}(n)||^2+\gamma(n)^2\left|\left|\sum_{i=1}^n\frac{\mathcal{E}_i}{\gamma_i}\right|\right|^2-2\gamma(n)\left\langle\mathcal{E}(n),\sum_{i=1}^n\frac{\mathcal{E}_i}{\gamma_i}\right\rangle\right) \\ &\leq \frac{1}{1-\frac{c^2}{nC^2}}\left(n^2M+\frac{C^2}{n^2}\left|\left|\sum_{i=1}^n\frac{\mathcal{E}_i}{\gamma_i}\right|\right|^2+2\frac{C}{n}\left|\left\langle\mathcal{E}(n),\sum_{i=1}^n\frac{\mathcal{E}_i}{\gamma_i}\right\rangle\right|\right)\end{aligned}$$

where $\gamma(n)$ and $\mathcal{E}(n)$ stands for the aggregate risk aversion and endowment of the n first agents. But, $\left|\left|\sum_{i=1}^n\frac{\mathcal{E}_i}{\gamma_i}\right|\right|^2 \leq \frac{1}{c}\,||\sum_{i=1}^n\mathcal{E}_i||^2 \leq \frac{n^2M}{c}$ and

$$\left|\left\langle\mathcal{E}(n),\sum_{i=1}^n\frac{\mathcal{E}_i}{\gamma_i}\right\rangle\right| \leq \frac{1}{c}\sum_{i=1}^n|\langle\mathcal{E}(n),\mathcal{E}_i\rangle| \leq \frac{1}{c}\sum_{i=1}^n||\mathcal{E}(n)||||\mathcal{E}_i|| \leq \frac{n^2M}{c}.$$

Therefore, we have the following estimation for the aggregated reported endowment of the n first agents

$$||\mathcal{B}^*(n)||^2 \leq \frac{M}{c}\left(\frac{cn^2+C^2+2nC}{1-\frac{c^2}{nC^2}}\right) \tag{50}$$

Also, $\sum_{i=1}^n\gamma_i\left(\frac{\gamma_{-i}}{\gamma_i+\gamma_{-i}}\right)^4 \leq \frac{C^5}{c^4n^3}$, which together with (50) implies that

$$\sum_{i=1}^n\gamma_i\left(\frac{\gamma_{-i}}{\gamma_i+\gamma_{-i}}\right)^4||\mathcal{B}^*(n)||^2 \leq \frac{MC^5}{c^5}\left(\frac{cn^2+C^2+2nC}{n^3-\frac{n^2c^2}{C^2}}\right) \to 0 \tag{51}$$

as $n \to \infty$. Continuing with the terms in (49), we have

$$\begin{aligned} \sum_{i=1}^n\gamma_i\left(\frac{\gamma_{-i}}{\gamma_i+\gamma_{-i}}\right)^3\langle\mathcal{E}_i,\mathcal{B}^*(n)\rangle &\leq \frac{C^4}{c^3n^3}||\mathcal{B}^*(n)||\sum_{i=1}^n||\mathcal{E}_i|| \\ &\leq \frac{C^4}{c^3n^2}\sqrt{M}||\mathcal{B}^*(n)|| \\ &\leq \frac{C^4}{c^{7/2}n^2}M\sqrt{\frac{cn^2+C^2+2nC}{1-\frac{c^2}{nC^2}}} \to 0 \qquad (52)\end{aligned}$$

as $n \to \infty$. From (49), (51) and (52) we get that the first term of (37) goes to zero as the number of agents approaches infinity.

Proof of Theorem 2

Taking Proposition 7 into account, we conclude that the market equilibrates when the covariances $\mathbb{C}\text{ov}(\mathbf{C}, B_i^*)$ equilibrate. As we have seen in Theorem 1, this may happen for endowments B_i^* given in (34), which gives price (40). The uniqueness of the Nash equilibrium price follows by the Standing Assumption 1.

The equivalence of Nash equilibrium price and the Pareto equilibrium price when agents have common risk aversion is then induced by Corollary 2 (see also equation (12)). Furthermore, (42) follows by Proposition 2.

Proof of Proposition 10

We assume as usual that expectations are equal to zero and from (12) and (40) we have that

$$||\mathbf{p}^*(n) - \hat{\mathbf{p}}(n)|| = 2\gamma(n)||\,\mathbb{C}\mathrm{ov}(\mathbf{C}, \mathcal{B}^*(n) - \mathcal{E}(n))|| \le 2\gamma(n)||\mathcal{B}^*(n) - \mathcal{E}(n)||\sqrt{\sum_{j=1}^{k}||C_j||^2},$$

where the notation is the one introduced in the proof of Proposition 8. Therefore, it is enough to show that $\gamma(n)||\mathcal{B}^*(n) - \mathcal{E}(n)||$ vanishes as $n \to \infty$. For sufficient large n, we have

$$\begin{aligned}
\gamma(n)||\mathcal{B}^*(n) - \mathcal{E}(n)|| &= \frac{\gamma^2(n)}{1 - \sum_{i=1}^{n}\left(\frac{\gamma(n)}{\gamma_i}\right)^2}\left|\left|\sum_{i=1}^{n}\frac{\gamma_i\mathcal{E}_i - \gamma(n)\mathcal{E}(n)}{\gamma_i^2}\right|\right| \\
&\le \frac{\gamma^2(n)}{c^2 - \frac{C^2}{n}}\left|\left|n\gamma(n)\mathcal{E}(n) - \sum_{i=1}^{n}\gamma_i\mathcal{E}_i\right|\right| \le \frac{C^2}{n^2c^2 - nC^2}\left(n\gamma(n)\,||\mathcal{E}(n)|| + \left|\left|\sum_{i=1}^{n}\gamma_i\mathcal{E}_i\right|\right|\right) \\
&\le \frac{\sqrt{M}C^2}{n^2c^2 - nC^2}\left(n^2\gamma(n) + nC\right) \le 2\frac{n\sqrt{M}C^3}{n^2c^2 - nC^2} \to 0
\end{aligned}$$

as n goes to ∞. For item (ii), we fix an agent i and from (13) and (42), it is enough to show that $||\,\mathbb{C}\mathrm{ov}(\mathbf{C}, C_i^*(B_i^*) - C_i^*)||$ goes to zero as $n \to \infty$. Following the steps above it suffices to show that $||C_i^*(B_i^*) - C_i^*|| \to 0$.

$$\begin{aligned}
||C_i^*(B_i^*) - C_i^*|| &= \frac{\gamma(n)}{\gamma_i}\left|\left|\mathcal{E}_i + \frac{\gamma_i - \gamma(n)}{\gamma_i}\mathcal{B}^*(n) - \mathcal{E}(n)\right|\right| \\
&\le \frac{\gamma(n)}{\gamma_i}||\mathcal{E}_i|| + \frac{\gamma(n)}{\gamma_i}||\mathcal{B}^*(n) - \mathcal{E}(n)|| + \frac{\gamma^2(n)}{\gamma_i^2}||\mathcal{B}^*(n)||
\end{aligned}$$

We have seen in the proof of item (i) that $\gamma(n)||\mathcal{B}^*(n) - \mathcal{E}(n)|| \to 0$. Also, since $\gamma(n) \le \frac{C}{n}$, $\frac{\gamma(n)}{\gamma_i}||\mathcal{E}_i|| \to 0$. Finally, taking into account (50), we get that $\gamma^2(n)||\mathcal{B}^*(n)|| \to 0$, which completes the proof.
